SMYTHE (SMITH), **SIR THOMAS** (1558?–1625), English entrepreneur, was pre-eminently instrumental in launching, financing and administering pioneer English joint-stock enterprises in overseas trade, colonial settlement and exploration during the first two decades of the 17th century. A member of the London Haberdashers' and Skinners' companies from 1580, he accumulated a considerable fortune from commerce. Besides holding other official posts, he was incorporator and for some years governor of the East India company, treasurer of the Virginia and Somers Islands (Bermuda) companies, governor of the Muscovy and French companies and ambassador to the tsar (1604–05). He was a prime initiator of voyages to discover a Northwest passage. Smythe's efforts and a good part of his fortune were consistently and selflessly devoted to experiments that underlay England's subsequent imperial and commercial greatness. Although there was some controversy as to his management of the Virginia company, his fame as the entrepreneur and supporter of outstanding ventures is secure. Smythe died at Sutton-at-Hone, Kent, on Sept. 4, 1625.

SNAIL, a name generally applied to any member of the class Gastropoda, the largest of the six classes of the phylum Mollusca (*see* MOLLUSK). The gastropods include land, fresh-water and marine forms, among them such well-known shelled groups as whelks, periwinkles, conchs, cones, limpets, abalones, land snails and pond snails. Land gastropods lacking shells commonly are known as slugs, and shell-less marine forms as nudibranchs or sea slugs (*see* SLUG). There is, so far as is known, only a single species of shell-less fresh-water snail.

This article on snails is divided into the following sections and subsections:

I. GENERAL FEATURES

Gastropods are primarily distinguished from other mollusks by the shell, which, when present, is a single structure (except in the Juliidae, which have a bivalved shell), spirally coiled, at least in the larval stage, and typically sufficiently large so that the animal may retract completely within for protection. In many forms, however, the shell is very much modified in the adult. It may be nearly flat, cup-shaped or tubular. In some forms the mantle may completely cover the shell and in others the shell may be entirely absent. Gastropods also are distinguished by having a well-defined

CY LA TOUR

FIG. 1.—COMMON GARDEN SNAIL (HELIX ASPERSA)

head region, which possesses one or two pairs of tentacles, eyes and a mouth with jaws, liplike folds and a rasping tongue, or radula. The foot usually is developed as a creeping organ, and locomotion is accomplished by continuing waves of muscular contractions. Respiration is carried on either by means of gills, a pallial outgrowth, a pulmonary sac or, as in a few groups, the entire body surface. In all snails, however, the entire body surface may function in respiration under adverse conditions.

Gastropods are further distinguished from other mollusks by their asymmetry. The vital organs are not paired nor are they lined up on a median axis with an anterior mouth and posterior anus as is the case with the classes Monoplacophora (*q.v.*) and Amphineura (*q.v.*; chitons). In the gastropods the visceral mass has been doubled in a loop so that the anus is brought forward close to the mouth. This is not a simple flexure, however, for there is also a 180° twisting of the loop posterior to the head, which causes the organs of the left-hand side of the animal to lie on the right side, places the anus above the mouth and twists the nervous system to form a figure 8. Associated with this radical twisting known as torsion, is the loss of the organs of the normal right side of a symmetrical animal (the post-torsional left side).

II. DISTRIBUTION AND HABITAT

Gastropods are among the most widely distributed of all groups of animals and the only mollusks that have adapted to life on land. The majority, however, occur in marine, brackish and fresh-water habitats. They are found from the depths of the ocean to the tops of high mountains in the tropics, from deserts to tropical rain forests and from small springs and ditches to large lakes and rivers. Some marine snails may live most of their lives well above the strand line on rocks, trees and even the sides of houses, returning to the water only to breed. Others, such as the littorines, are found in the intertidal zone, where they are covered by water much of the time but are exposed during low tide. The majority of the littoral, or shore, species, however, are found at or just below the low-tide mark, for they cannot tolerate long periods outside the water. Such species, however, often may be found in tide pools. Many species found at considerable depths can be obtained only by dredging.

1. Marine and Brackish-Water Snails.—Water temperature, salinity and the type of substrate are the most important factors controlling the distribution of marine snails. Some species found in the intertidal zone in cold waters often can be obtained by dredging in adjacent warmer waters, the snails moving out into cooler, deeper water. Species requiring full marine conditions will not be found near the mouths of rivers pouring large amounts of fresh water into the sea. A stable brackish-water area has a unique gastropod fauna not found in other areas, but an area that fluctuates between brackish- and salt- or fresh-water conditions is usually barren. The type of bottom is an important factor controlling distribution, for some species require a sandy or muddy bottom, while others are restricted to rocky shores. A long

stretch of sandy shore may completely block the distribution of rock-loving forms that might otherwise be able to live there. Pelagic forms are widely distributed, their distribution being controlled mainly by temperature. Many species of parasitic marine snails are restricted by their feeding habits, which may limit them to a single host species.

Most families of marine snails have a wide range of distribution, but some genera and many species may be very restricted. Families such as the Cypraeidae (cowries) are found in nearly all tropical and warm temperate seas but reach their greatest numbers in the vast Indo-Pacific area. The four great oceanic regions—the eastern Atlantic, the western Atlantic, the eastern Pacific and the Indo-Pacific—have been divided into numerous subregions, each with gastropods peculiar to it, the controlling factor being temperature, usually that which is suitable for the breeding and survival of the young. Certain intertidal areas, such as the coast of the United States from Virginia to South Carolina, may have a rather poor molluscan fauna, for the range of temperature from the summer high, which may reach 85° F. (about 29° C.), to freezing winter temperatures is too great for most species. Snails with a free-swimming larval stage are generally more widely distributed and the populations more uniform than those that emerge from the egg capsule as young, crawling snails.

2. Land Snails.—In the cooler regions of the world, land snails are usually rather inconspicuous, brownish and fairly small. As a rule they live on the ground or on low shrubs or grass, feeding mainly on detritus (organic debris). They burrow into the ground during the winter for protection and generally lay their eggs there. In desert areas snails are usually light coloured and heavier shelled. Most species burrow into the ground during the dry season for protection, but some cement themselves to the trees or rocks by a limy mucus secretion. They become very active when the rains begin, feeding voraciously and breeding. In the warm temperate and tropical regions, where there is sufficient moisture, the snails will remain active throughout the year. Land snails are most abundant in areas where there is plenty of limestone; some species, in fact, may be found only on limestone rocks, where they feed on lichens. In general, insular areas are richer in land snails than are the continents, perhaps a reflection of the reduction of predators on islands. Probably the richest land snail area in the world is the island of Cuba, but the largest land snails are found in Africa (*Achatina*) and in South America (*Strophocheilus*). In general, tree snails such as *Liguus* in Florida and Cuba and *Helicostyla* in the Philippines are highly coloured, while ground-living forms are drab. The distribution of land snails on islands is often fortuitous, the snails being carried as eggs or young snails by man, birds, hurricanes or by rafting.

3. Fresh-Water Snails.—Fresh-water snails are found in nearly all permanent bodies of water, regardless of size, though they are rare and small in areas without limestone and in fast-flowing streams in the colder portions of the world. Swift streams in warmer regions may be very rich in mollusks, particularly in areas of abundant limestone. The southeastern United States is perhaps the richest area in the world for fresh-water snails. This area is old geologically and was not glaciated; thus, the snails have had time to evolve many genera and species peculiar to the rivers of this area, the Coosa river of Alabama being the most remarkable. Lakes are generally transient and seldom have species peculiar to them. There are, however, several very old lakes that support remarkable snail faunas. Most famous of these is Lake Tanganyika in Africa, which has a large number of endemic genera and species of mollusks. Because the physical characteristics of this large, deep lake approximate those of the ocean and because some of the snails resemble marine forms, Lake Tanganyika was long thought to have had a marine origin. Most of the snails, however, belong to the local fresh-water family Thiaridae (or Melaniidae). Fresh-water snails may be carried from one stream or pond to another as eggs or young snails on the feet of water birds; they may be blown with leaves or carried by floods. Most fresh-water snails cannot withstand submergence in salt water, so migration from one stream to another via the sea is virtually impossible.

III. IMPORTANCE

1. Economic Importance.—Gastropods are not as important a source of food for man as are the bivalves, but a number of species are eaten. The Roman land snails or *escargots* (*Helix pomatia* and *H. aspersa*) are considered a delicacy, particularly in France; as in Roman days, these snails often are raised in special gardens called cochlearia. Many species of marine snails are eaten in various parts of the world, particularly by the poorer classes. Among those more commonly eaten are the periwinkle (*Littorina littorea*) in Europe, the top shell (*Livona pica*) and the conch (*Strombus gigas*) in the West Indies. The flesh of conchs is used to make a delicious chowder. In California and Australia the large foot of species of abalone (*Haliotis*) is tenderized and served as a steak. Abalone is often canned and can be purchased in the markets. In some portions of Africa the large land snail *Achatina* is an important item of food for the natives. *Achatina fulica* was introduced into many of the Pacific islands by the Japanese.

Tremendous numbers of larger gastropods such as the whelks are used as bait by fishing fleets, particularly on the long lines, for the tough, muscular foot is not easily torn from the hook.

To the paleontologist and the oil geologist snails are important as index fossils, and a study of the distribution and habits of living forms aids in the interpretation of the events of the past.

Gastropods long have played an important role in the jewelry market. The beautiful, iridescent, highly coloured shells of the abalone are used in inlay work and in the manufacture of rings, pins, earrings and buttons. The Japanese collect *Trochus* shells of the Indo-Pacific by the ton for use in the button trade. *Cassis rufa* of the Red sea is the shell most commonly used in the manufacture of cameos. Here the great difference in the colour of the two shell layers is utilized, the figure being cut in the light outer layer while the dark-reddish inner layer serves as a background. Pearls occasionally found in gastropods, though they may be very beautiful, generally are irregular and not of great economic importance. Those found in the lower gastropods with iridescent shells have a lasting pearly lustre, but the beautiful pink pearls

FIG. 2.—SNAILS OF DIFFERENT HABITATS

(Above) The eyeless purple snail (*Janthina janthina*) drifts on the warm ocean surface buoyed by a "raft" of air cells and mucus; (right) the tree snail (*Liguus fasciatus*), common to Cuba and parts of Florida, glides on a mucous film it secretes on the bark of trees

of *Strombus* eventually fade and lose much of their beauty.

Among native tribes various species of snails have been used as money, the most famous being the money cowrie (*Cypraea moneta*) of the Indo-Pacific. Shells, particularly cowries, are used for adornment by the natives of New Guinea, the Fijis and other Pacific islands. The rare and beautiful golden cowrie (*C. aurantium*) is a badge of office and may be worn only by chieftains. Snails also are found in religious ceremonies; the triton trumpet (*Charonia tritonis*) is used by the Shinto priests of Japan to call the people to worship, and in India the left-handed chank shell (*Xancus rapa*) is considered sacred. The Tyrian or royal purple dye of the Phoenicians was a product of the common *Murex* species of the Mediterranean and was a most important item in the economy of the people. The Mexican natives dye cloth with the exudate of the snail *Thais patula pansa*. (*See* also SHELLS AND SHELL COLLECTING.)

2. Ecological Importance.—The place of gastropods in nature is very important. As free-swimming larvae they are eaten by larger planktonic animals such as shrimp and small fish. Many of the bottom-feeding marine fishes and a few fresh-water fishes feed almost entirely upon mollusks (in fact, fish stomachs are a good source of shells not generally found in the intertidal zone). Many ducks and other water birds also feed on snails.

From a negative point of view snails are far more important, for many of them, especially fresh-water forms, are intermediate hosts of trematodes (flatworms or flukes), which are parasitic in man, cattle, sheep and various other mammals as well as in birds. In man the most important of these trematode diseases is schistosomiasis (*q.v.*), the blood fluke disease, which in various forms occurs in Africa, the near east, China, Japan, the Philippines, Brazil and in certain of the West Indies, where it has been introduced. Probably most snails are the intermediate hosts of some fluke, but fortunately most of them do not affect man directly. Eliminating the snail host is still the best means of controlling these diseases. In areas where the poorer classes use the streams, lakes and ponds for washing clothes, bathing and in religious rites, the education of the people concerning the disease and its spread is of some help. (*See* also FLUKE.)

Many snails are predators, feeding particularly on bivalves; they may be very destructive to the commercially important clam and oyster beds. The slipper limpet (*Crepidula fornicata*) was accidentally introduced into Europe, where it has caused considerable damage by smothering the oyster beds.

The cone shells (*Conus*) are not normally harmful to man but, if improperly handled, can inflict a fatal wound. The radula ribbon in this group is highly modified and is associated with a poison gland. Cones are sluggish snails and their dartlike teeth and poison are normally used in subduing prey.

IV. STRUCTURE AND FUNCTION

1. Basic Body Plan.—Though the anatomy of the various groups of gastropods appears superficially very different, in reality the many patterns are only variations of a basic theme. Once the stylized gastropod (fig. 3) is understood it is possible to follow the arrangement through with its increasing elaborations, reductions and changes from the generalized to the highly specialized forms.

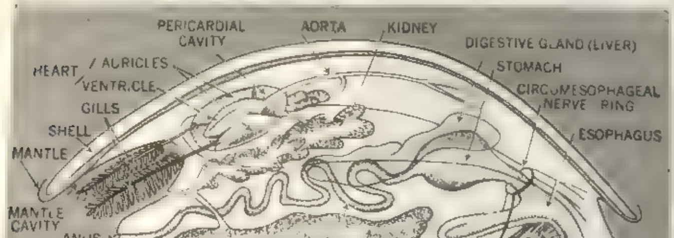

FIG. 3.—HYPOTHETICAL PRE-GASTROPOD SHOWING PROBABLE POSITION OF ORGANS BEFORE FLEXURE AND TORSION

It is impossible, of course, to know the complete anatomy of the first gastropods, for they are known only as fossils. However, it was probably similar to that of a monoplacophoran and so had a caplike shell, a large, flat foot developed for creeping or clinging to the substratum, a head region with a mouth and radula but probably lacking eyes and tentacles. The mantle was probably a simple "cape" hanging over the dorsal surface of the animal and extending just beyond the edge of the shell. The muscle attaching the animal to the shell was probably U-shaped, open in front. Internally the earliest gastropod was probably bilaterally symmetrical; however, unlike a monoplacophoran, it must have had only a single pair of each of the vital organs such as gills, kidneys (nephridia) and reproductive organs. The nervous system undoubtedly had two sets of parallel nerves—a dorsal ring serving the visceral mass and a ventral one with a ladderlike arrangement in the foot. The heart was at the posterior end of the animal; the ventricle in the centre with an auricle on each side (fig. 4).

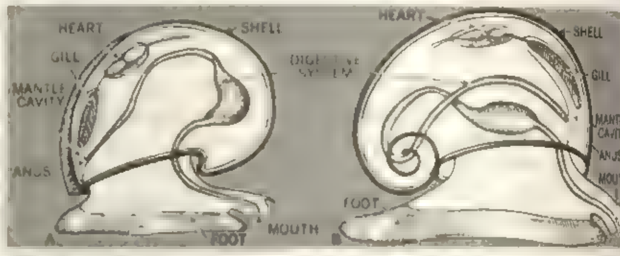

FIG. 4.—(A) POSSIBLE ARRANGEMENT OF AN EARLY GASTROPOD BEFORE TORSION; (B) PROSOBRANCH GASTROPOD SHOWING TORSION

The gills were located in a groove or cavity posterior to the heart and between the mantle and the foot. The paired kidneys and reproductive organs had common openings near the base of the gills.

The sexes were separate but could only be distinguished by the colour and products of the gonads. The coils of the long intestine were probably interwoven with the gonads.

If this hypothetical, bilaterally symmetrical animal is doubled into a loop and twisted in 180°, the result is the basic anatomy of the gastropod. Torsion takes place during the veliger stage of development, observable in the embryo (fig. 5). The earliest

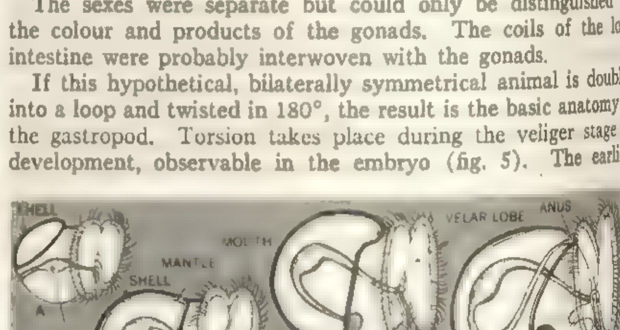

FIG. 5.—FLEXURE AND TORSION OF VELIGER: (A) BEFORE BEGINNING OF FLEXURE; (B) AT TIME OF FLEXURE AND BEGINNING OF DEVELOPMENT OF FOOT; (C) JUST BEFORE TORSION; (D) AFTER TORSION

gastropods soon gave rise to forms with coiled shells, which in the process of evolution were first bilaterally symmetrical and so planispiral (coiled in a single plane), and later asymmetrical with a protruding spire. This type of shell was very successful and has persisted; it is compact and strong and at the same time portable affording mobility and protection.

2. Shell.—The shell is carried dorsally and is usually large enough so that the animal may retreat within it completely. Like that of bivalves, the shell is typically composed of three layers. The inner layer is further laminated; in some it may be nacreous or iridescent. It is laid down by the entire surface of the mantle. The outer prismatic layer is produced at the growing edge of the shell (the lip) and is laid down by cells at the outer edge of the mantle. Prolongations of the mantle at the lip may extend out to produce spines, nodules or other sculptural features.

The outer surface of the shell in most species is covered by a protective coating of periostracum, a chitinlike material that ranges from a thin, smooth and nearly transparent layer to a thick and hairy covering. The periostracum is produced in a special fold in the outer edge of the mantle. The ability to produce

colour is invested in all three layers. The laminated layer in genera such as *Haliotis, Patella, Cypraea* and *Cassis* may produce various colours, and in *Haliotis* and *Patella*, which are nacreous, additional iridescent colour effects are produced by the structural arrangement of the component layers. In most groups colour is produced in the prismatic layer uniformly or in the form of strips or bands, either spiral or axial, in spots, zigzag lines or irregular blotches. The periostracum in most groups is some shade of yellow or brown, sometimes being nearly black. In a few forms, such as the highly coloured tree snails, other hues, particularly green, rare in mollusks, may be produced in the periostracum. Very little is known about the physiology of colour production in mollusks, and nothing is known concerning the mechanism by which the complicated colour patterns of some species are made. In addition to the shell many forms have a calcareous or horny plate, the operculum, which is produced on the dorsal surface of the foot and which closes the aperture when the animal retreats within the shell. Pulmonates—lunged snails of fresh water and land—do not have an operculum, the aperture of some species usually being closed by a limy secretion from glands in the foot. The animal is attached to the shell by means of a large, powerful muscle attached to the central pillar or columella of the shell. The various shapes as well as sculptural and colour patterns produced by snails are almost infinite; it is these characters on which species, most genera and some families are based. However, since the same general forms may appear in widely separated families, the shells cannot be used in the classification of higher categories.

3. Digestive System and Feeding.—Snails feed in a number of different ways and on a variety of food. All snails, except the adults of some parasitic forms, have a radula, which is used in procuring food. It is ribbonlike and on the outer surface armed with numerous rows of teeth (fig. 6). Worked by muscles, it functions as a rasping organ and a conveyor belt to carry the food back into the mouth and esophagus. Many groups also have horny jaws with which to cut off small particles.

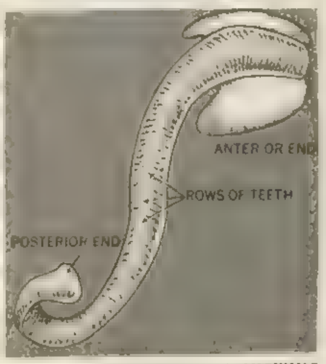

FIG. 6.—RADULA RIBBON SHOWING TRANSVERSE ROWS OF TEETH

The earliest gastropods were probably very unselective in their feeding, merely scraping in bottom detritus containing organic material. Among the least specialized snails of the subclass Prosobranchia are the archeogastropods (order Archeogastropoda), most of which are plant feeders, browsing on the algal film on rocks or feeding on larger algae. In their browsing, however, they also may scrape up some small encrusting bryozoans and sponges. Land forms (family Helicinidae) feed on algae and lichens that form a film on the trees and rocks. The order of mesogastropods includes detritus feeders, plant feeders, scavengers, predators and parasitic forms. Some are filter feeders and use the gills in a manner similar to that of bivalves. By means of cilia and mucus on the gills these species filter the minute particles of food from the water brought into the mantle cavity. The food is collected in mucous strings that are carried by means of cilia to the mouth and are pulled in by the radula. Some attached snails such as the Vermetidae use mucous traps to catch their food. Thin sheets of mucus are extended into the water where they wave about and collect minute organisms and floating debris. The radula pulls the mucous sheet back into the mouth and it is eaten.

Most of the large mesogastropods, such as the cowries, conch shells (Strombidae), cameos (Cassidae) and cask shells (Tonnidae), feed mainly on echinoids and bivalves. Cowrielike *Trivia* and *Erato* have developed a proboscis that can be extended into the mouths of the encrusting colonial tunicates on which they feed. Some cowries have a varied diet and one species has been observed feeding on algae, sea anemones, sponges, dead and decaying mollusks or fish and even the eggs of other snails.

Some mesogastropods are scavengers feeding on dead animal matter, while others (*e.g., Hipponyx*) have formed a commensal relationship, living on the shells of turbinids and feeding on their fecal pellets.

The scavengers and browsing forms that fed on encrusting animals probably led the way toward the carnivorous habit. Among the mesogastropods the Naticidae (moon shells) and Pterotracheidae (heteropods) are true carnivores that actively hunt their prey. The moon shells drill neat, round holes in the shells of bivalves, insert their proboscides and devour the soft parts within. The heteropods can swim and actively catch the small fish and other animals on which they feed.

All neogastropods (order Neogastropoda) are flesh eaters, either scavengers or carnivores, and many combine both habits. Scavengers such as *Nassarius* often may be seen in numbers approaching a dead fish, which they can detect from some distance, gathering in large numbers to feed at a common table. Baiting such forms by staking out a dead fish is often a successful way to collect them.

Opisthobranchs also show the complete range of the feeding habits found in the prosobranchs; the lower types are generally plant and detritus feeders, while the higher forms are scavengers and carnivores. Notes on their feeding habits are included under the section on the major groups, below.

The subclass Pulmonata includes mainly plant and detritus feeders, though *Euglandina, Streptaxis* and some of the slugs are carnivorous. They feed on worms, insect larvae and other snails and their eggs. Ground-living pulmonates such as *Mesodon* (Polygyridae) often are found feeding on mushrooms. Some species of helices are capable of digesting cellulose by means of an enzyme produced by certain intestinal bacteria.

The few species of gastropods that are completely parasitic are quite small. Many species in the Eulimidae are parasitic on sea urchins, starfish and sea cucumbers. The tips of their white shells often may be seen protruding slightly from the surface of their host. The young eulimid has a typical radula with which it bores into its host, but the radula is soon lost and the snail feeds by sucking the body juices of the host. Most species in the Pyramidellidae are now thought to be parasitic; this group has developed elaborate mouth parts adapted for puncturing the host and sucking the body juices. The most highly specialized of the parasitic snails is *Entoconcha*, which lives in the gonads of the sea cucumber. These snails have lost the radula, jaws and shell and look more like worms than mollusks, but the young have a well-developed shell and even an operculum, features that are definitely gastropodan.

V. REPRODUCTION AND DEVELOPMENT

1. Breeding Habits.—Fertilization in a few opisthobranchs and in many of the lower groups of gastropods may be external, but in most forms it is internal and there is usually a male intromittent organ. The embryonic stages include trochophore and veliger larvae, which may be free-swimming or enclosed within a gelatinous covering or egg capsule, or the eggs may be retained within the body of the parent until the young are fully developed and emerge as diminutive crawling snails.

2. Embryology and Development.—In all gastropods, cleavage of the egg is complete. In groups lacking yolk it is possible to follow the early cleavage stages of living embryos with the aid of a microscope. The first larval stage, the trochophore, usually lasts only a few hours; it is variable but commonly has a ring of cilia around the broad portion with a tuft of cilia at either end. During the second larval stage, the veliger, the embryonic shell is developed. Generally those species having a long, free-swimming larval life have large velar lobes with strong cilia that are used in feeding. Species with such larvae usually are widely distributed. In species with a short, free-swimming larval life, usually those that produce their eggs in gelatinous strings or masses, the velar lobes are smaller and not so elaborately developed. Such forms use the larval stage mainly as a means of dispersal rather than feeding.

LYNWOOD M. CHACE

FIG. 7.—SLUG LIFE CYCLE

Stages in the life cycle of the black slug (*Limax*), a hermaphroditic pulmonate: (left) pair of slugs, having lowered themselves from a branch by means of a mutually produced mucous string, intertwine and mate while suspended; (above) the shiny, gelatinous eggs are laid in clusters in sheltered places; (right) eggs and recently hatched slugs, tiny replicas of the adults

Many snails produce their eggs in capsules within which the young may spend their entire larval life. Eggs of such forms may have a large yolk supply, or the capsules may contain nurse eggs on which the developing young feed. The shell of the veliger, which usually differs markedly from the adult shell both in structure and sculpture, often may be seen at the apex of older specimens. Generally speaking, if the veliger shell is composed of several whorls, the larval stage has been a long one. Those species with a short larval life have shells with few whorls, usually only one or one and a half. Larvae that are retained within the egg capsule apparently use their velar lobes to create currents in the capsular fluid as an aid in respiration and to keep themselves distributed throughout the capsule. Some groups of land snails have calcareous egg shells. A few fresh-water forms (the Viviparidae) retain the eggs within the body of the parent until the time of hatching and the young emerge as tiny snails; such species are referred to as ovoviviparous.

VI. EVOLUTION AND RELATIONSHIPS

On the basis of comparative anatomy and embryology, definite natural groups of gastropods have been established and the relationship of most of the groups determined. The difficulty in studying gastropod evolution is in relating the recent to the fossil forms. As has been shown, the shell is not a reliable indicator of classification above the generic level. As a consequence paleontologists have never attempted to work out a classification of gastropods based on shell characters, as has been done with bivalves. Instead they have fitted gastropod families, genera and species into higher categories provided by the students of recent mollusks.

The recent discovery of *Neopilina,* a living monoplacophoran (*see* MONOPLACOPHORA), has shown that all limpetlike fossil shells cannot be classed as gastropods. However, *Helcionella,* a limpetlike genus of the Cambrian period, generally is considered to be a primitive gastropod that had undergone torsion but had a caplike shell. The bellerophontids (*Owenella*) of the Upper Cambrian and Lower Triassic were perhaps the next step in evolution; the shell, though bilaterally symmetrical, is planispiral. The slit at the aperture of these shells is very similar to that of the Pleurotomariidae, and most paleontologists today believe that it functioned as an anal slit, as it does in the recent forms; therefore, it is quite reasonable to believe that the animals had undergone torsion.

The first asymmetrically coiled shells probably arose from the bellerophontids as a result of the protrusion of the early whorls to the right or left to form the apex of the spire. In most forms the protrusion was to the right, producing a dextral, or orthostrophic, shell; those that protruded to the left are sinistral, or hyperstrophic. In Upper Cambrian times a group arose that can be traced in a direct line to the present-day Pleurotomariidae; these were undoubtedly the ancestors of present-day prosobranchs.

It is generally believed that the Opisthobranchia arose from some archeogastropod stock such as the trochoids in which the right pallial organs have been lost. The opisthobranchs are believed to be monophyletic (derived from a single line) because all forms have a sinistral larval shell even though the adult shell, when present, is dextral. The Pyramidellidae and Acteonidae are more nearly allied to the prosobranchs than are other opisthobranchs, but they clearly belong in this subclass because of the sinistral larval shells, the anatomy of the digestive tract and the occurrence of hermaphroditism. The ancestors of these families, which were probably transition forms between the prosobranchs and the opisthobranchs, are known at least as far back as the early Carboniferous. The pteropods appear to be opisthobranchs that have retained the pelagic habit throughout life. The nudibranchs probably arose at a much later period from more than one group of opisthobranchs.

The pulmonates are generally considered to be close to the opisthobranchs and probably arose from some early opisthobranch stock or from some archeogastropod stock close to that from which the opisthobranchs arose. The earliest reliable pulmonate record is from the Carboniferous. There is still some question about the placement of the order Systellommatophora. Some authorities place it in the Opisthobranchia and others in the Pulmonata.

There is no question that they are transition forms between the two subclasses, but since two of the three families included in the order appear to be closer to the Pulmonata, they are included in that order here. However, a great deal more work needs to be done on this obscure group before definite placement can be made.

VII. SURVEY AND CLASSIFICATION

Many factors are taken into consideration when attempting to arrange gastropods into natural groups. No one character can be used alone. Consequently it is little wonder that there is no one classification universally agreed upon by all workers. No attempt will be made here to discuss the various theories or to give a detailed classification of the gastropods but only to outline the major groups which seem to be most universally accepted. For those interested in pursuing the subject further, the references listed in the bibliography will be of help.

The class Gastropoda is divided into three subclasses on the basis of the nervous, respiratory, circulatory and reproductive systems. The nervous system becomes progressively more concentrated, the reproductive system more complex and the respiratory system more specialized, beginning with the oldest known group,

the archeogastropods (subclass Prosobranchia) which are known from the Cambrian, and progressing upward through the opisthobranchs (subclass Opisthobranchia) to the Stylommatophora (subclass Pulmonata), which first made their appearance in the Upper Cretaceous.

Subclass Prosobranchia
  Order Archeogastropoda

    " Basommatophora
    " Stylommatophora

1. **Prosobranchia.**—In the first subclass, the Prosobranchia (*proso*, "forward"; *branchia*, "gills"), the gills, when present, are located in front of the heart. Where the gills are absent, respiration is carried on by a special outgrowth of the mantle (Patellidae), or a simple pulmonary chamber in land species (Helicinidae). All prosobranchs show evidence of torsion, the visceral mass and nervous system being twisted to form a figure 8; hence this group is often referred to as the Streptoneura. An operculum is present except in those groups with caplike shells or shells with very large apertures as in abalones (Haliotidae). There is only one pair of tentacles with the eyes at the base (fig. 8). The foot is usually large, developed for creeping or holding fast to the substrate. The radula, present in all but the parasitic forms, is varied and can be used in grouping the prosobranchs into orders. The sexes are separate, and in higher forms the males have a large copulatory organ.

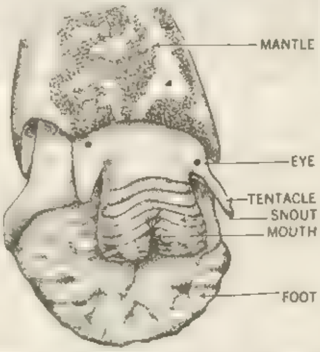

FIG. 8.—ANTERIOR END OF PROSOBRANCH SNAIL (TRUNCATELLIDAE) EMERGING FROM SHELL WITH FOOT STILL FOLDED

This subclass contains mainly marine species; of the approximately 90 families of prosobranchs only three are restricted to land and four to fresh water. Some families, such as the Bulimidae, are found in both marine and fresh-water habitats, and the Truncatellidae are found near the high-water mark at the edge of the sea (*Truncatella*) or on land (*Geomelania* and *Taheitia*). The Neritidae, though mainly marine, may be found also in fresh water and on land. The subclass is divided into three orders on the basis of the shell and radula and the nervous, respiratory and reproductive systems.

Archeogastropoda.—This order contains the oldest and least specialized of the gastropods (fig. 9). Other than the families Neritidae and Helicinidae, which are highly specialized, the archeogastropods are entirely marine and are characterized, in most families, by their pearly shells. The shell may vary in shape from typically top-shaped, spirally coiled shells, as in the Pleurotomariidae, Trochidae and Turbinidae, to a flattened coil, as in the Haliotidae, or a volcano- or cap-shaped shell that has lost all evidence of its early coiling and again become outwardly bilaterally symmetrical, as in the Fissurellidae, Acmaeidae and Patellidae. The foot is large and the operculum, in most of the trochoid forms, may be calcareous or horny. Respiration is by means of single or paired bipectinate gills, free at the anterior end, by a pallial outgrowth (Patellidae) or by a modified pulmonary sac (Helicinidae).

The archeogastropods, mainly plant feeders, have specialized radulae. The rhipidoglossate radula found in most families is a long, wide ribbon with strong lateral teeth for scraping and numerous long, weak marginal teeth for carrying the minute particles into the mouth. The docoglossate radulae found in the Acmaeidae and Patellidae are close to those found in the chitons; both these families feed in much the same manner as do the chitons.

FIG. 9.—SUBCLASS PROSOBRANCHIA, ORDER ARCHEOGASTROPODA, SHOWING REPRESENTATIVE GENERA AND FAMILIES AND CHARACTERISTIC DENTITION

The twisted nervous system is much less concentrated than in other prosobranchs. There are no large ganglia in the head region. In most species the ladderlike arrangement of nerves in the foot is similar to that found in the chitons. The eyes are open, being only retinal pits lacking both cornea and lens, though in a few forms the opening is small and the pit is filled with a vitreous body bathed with water. Many archeogastropods retain much of the original bilateral symmetry, having two pectinate gills, two kidneys and a heart with two auricles.

The sexes in all groups of archeogastropods are separate, and in all except the Neritidae and Helicinidae there is no true penis or oviduct, the reproductive products being passed out through the modified right kidney. The sexes in these groups can be distinguished only by the colour of the sex organs or their products. The male organs are usually cream coloured, while the female organs are more brightly coloured. In many archeogastropods, as in some species of *Haliotis* and *Patella*, the eggs and sperm are shed into the water and fertilization is external. In such groups the eggs lack a protective covering, or have only a thin, gelatinous covering. Other groups deposit eggs in gelatinous ribbons that are attached to the substrate. The life span of the free-swimming larva varies greatly: in some forms the trochophore and veliger stages are passed within the egg; others have only a free-swimming veliger; and for a few the trochophore and veliger are planktonic.

Mesogastropoda.—This is a varied order that contains land, fresh-water and marine forms (fig. 10). Some species cement their shells to the substrate; others are completely pelagic. There are filter feeders, plant feeders, carnivores and parasites. Some are only a few millimetres in length when fully adult, while the giant *Megalatractus*, the false trumpet shell of Australia, reaches over two feet in length. Some are completely smooth (Naticidae) and others have an elaborate sculpture of spines (Muricidae). The cowries (Cypraeidae) cover the shell with the mantle and have highly polished shells, while the tritons (Cymatiidae) have a heavy, hairy outer coat of periostracum. Some are restricted to the intertidal zone; others are found only in the abyssal depths. Many are intermediate and have a considerable range.

Though most families have spirally coiled shells, in a few groups such as the Capulidae (the cap shells) and the Calyptraeidae (the

slipper limpets) the shell has become flattened and limpetlike or disc-shaped. The shell is never pearly and there is usually an operculum, which may be calcareous or horny.

In this order the nervous system is more concentrated around the esophagus and there is only a single, large pedal ganglion; however, the visceral loop is still in the form of a figure 8. The eyes are always closed and there is a well-developed cornea. There is no evidence of bilateral symmetry, the organs of the pretorsional right half of the animal having disappeared completely. Respiration is generally by means of a single, large monopectinate gill, which is attached throughout its length. In terrestrial families such as the Cyclophoridae and the Pomatiasidae the pallial or mantle cavity is transformed into a lung, while in the fresh-water family Ampullariidae both a gill and pulmonary sac are present, separated by an incomplete septum. There is a single kidney usually opening through a slitlike aperture. The heart has only a single auricle.

The sexes are separate, except in the Cerithiacea, and the male has a well-developed and often large copulatory organ. The genital opening is separate, the reproductive products no longer passing out through the kidney. Fertilization is internal and the eggs may be deposited singly, in gelatinous masses or strings, or in a variety of egg capsules.

The radula is usually taenioglossate, consisting of a large central tooth, two lateral teeth and four marginal teeth, but in the Epitoniidae and Janthinidae it is ptenoglossate, being composed of more or less uniform teeth, the central tooth lacking. The shorter, narrower, more strongly toothed radulae of the mesogastropods foreshadow the powerful radula of the carnivorous Neogastropoda. Some families of mesogastropods, such as the Naticidae (the moon shells), the Pterotracheidae (the heteropods), some of the cowries (Cypraeidae) and the tonnas (Tonnidae) are carnivorous. The heteropods are pelagic, fast-swimming animals that catch and feed on small fish, copepods, jellyfish and other planktonic animals. Most mesogastropods, however, are rather sluggish, grazing animals feeding on detritus, plants or encrusting animals such as sponges and bryozoans. In parasitic species the radula may be absent in the adult.

Neogastropoda.—The third order of the prosobranchs, the Neogastropoda, is entirely marine (fig. 11). All have well-developed, solid, spirally coiled shells, though a few, with very large apertures,

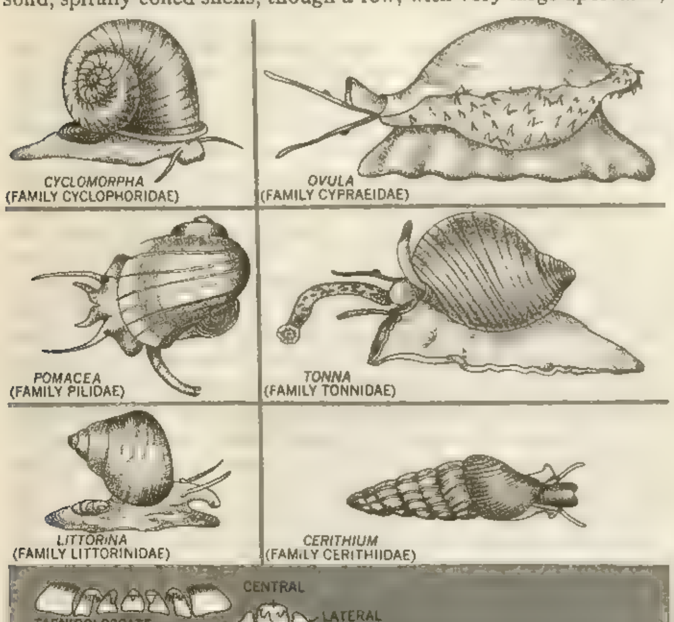

FIG. 10.—SUBCLASS PROSOBRANCHIA, ORDER MESOGASTROPODA, SHOWING REPRESENTATIVE GENERA AND FAMILIES AND CHARACTERISTIC DENTITION

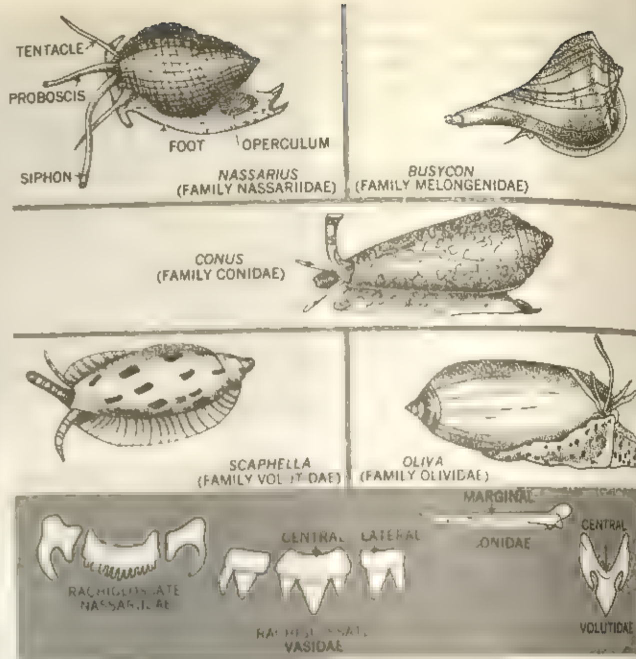

FIG. 11.—SUBCLASS PROSOBRANCHIA, ORDER NEOGASTROPODA, SHOWING REPRESENTATIVE GENERA AND FAMILIES AND CHARACTERISTIC DENTITION

have become somewhat flattened. The operculum, when present, is always horny and has few spirals. The neogastropods are all carnivorous. In most forms there is a well-developed proboscis that can be everted into the aperture of other gastropods, into the substrate to feed on worms or into the testes of echinoderms, etc. The radula is a short, narrow ribbon usually with only three large strong teeth per row—a central tooth and two lateral teeth. In some forms such as the Volutidae only the central tooth remains, and in the Toxoglossa (the Terebridae and Conidae), considered the highest group of the prosobranchs, the central and lateral teeth are lacking and the remaining marginal teeth are highly specialized. The teeth are needlelike and hollow, forming a minute hypodermic, usually with a barb at the end. In the Conidae the associated poison gland produces a powerful neurotoxin used to immobilize prey. The nervous system in the neogastropods is increasingly more complex; the visceral loop is still in the form of a figure 8, but the two intestinal ganglia come to lie close to the pleural ganglia in the head region. In this order the osphradium, a chemical sense organ, which lies near the gill, is usually double and highly developed. The sexes are separate, and the males have a large copulatory organ. Fertilization is internal; the eggs may be protected by a variety of egg cases or capsules, and the young may emerge in the late veliger stage or as young crawling snails.

2. Opisthobranchia.—In the second subclass, the Opisthobranchia (*opisthen*, "behind"; *branchia*, "gill"), the gills are behind the heart, though in many forms the gills are lacking and respiration is carried on over the entire surface of the body (fig. 12). The visceral loop and nervous system are not twisted into a figure 8, except in the Acteonidae (this group has undergone a secondary detorsion and so is often referred to as the marine Euthyneura). The nervous system is more concentrated around the esophagus, though there are still visceral and pedal ganglia that are connected by long commissures. The shell is greatly reduced or lacking, except in the Acteonidae, Bullidae and Pyramidellidae, though it is present in all forms in the larval stage. It is often flattened and platelike or ear-shaped and it may be partly or entirely internal. An operculum is present only in the Acteonidae and Pyramidellidae. All opisthobranchs are hermaphroditic.

There are usually two pairs of tentacles, though the posterior pair are more properly referred to as rhinophores, their function being olfactory. The foot is variously developed in the several orders as a creeping or swimming organ. As most opisthobranchs have little or no shell, the fossil record is limited, but they are known at least as far back as the Carboniferous and may go back

as far as the Upper Cambrian. Included here are the sea hares and their relatives, the nudibranchs, or sea slugs, and the pteropods, or sea butterflies.

The opisthobranchs are the least-known gastropods and their classification the most disputed. The number of orders recognized may vary from three to eight, depending upon the authority, but the general order in which the approximately 70 families are arranged, except in a few cases, is much the same. The classification most generally followed is that of Odhner.

Cephalaspidea.—Members of the order Cephalaspidea are characterized by usually having a well-developed external shell, though it may be internal or even absent. The head has a large shield or disc used for digging or plowing in the mud or sand in which the animals live. There are no tentacles, the eyes being sessile. The primitive Cephalaspidea such as *Actaeon* are mainly detritus feeders, but the more advanced forms have a radula developed for seizing prey and a muscular gizzard with horny or calcareous plates for crushing the prey, which is swallowed whole. The larger species may feed on bivalves and other gastropods; the smaller ones on foraminifera, worms, etc. This order includes the bullas or bubble shells, which have large apertures but lack opercula. Only in the Acteonidae, the most primitive of the group, is the operculum present. The nervous system is still twisted in a figure 8. In all other families in this order the visceral mass has become detorted, but the visceral loop is large and the nerves have not become highly concentrated around the esophagus.

Anaspidea.—Anaspidea lack the cephalic shield or disc; the shell is reduced, becoming largely or completely internal or lacking. The head has two pairs of tentacles; the large posterior pair, rhinophores, are olfactory organs; the short anterior pair are tactile organs. The eyes are sessile and are located just in front of the rhinophores. The foot is large, extending forward, anterior to the head and posteriorly beyond the visceral mass. Parapodia or swimming lobes, about midway on the dorsal surface of the foot, are fleshy, mobile flaps that cover the visceral hump when the animal is resting or crawling but can be moved in an undulatory way when the animal is swimming. Members of this group are known as sea hares, their large rhinophores giving them a rabbit-like appearance. Many species in this group emit a purple dye when disturbed. They feed mainly on seaweeds such as *Ulva* and *Fucus* and are capable of adapting their colour to match the seaweed on which they are feeding.

Pteropoda.—The order Pteropoda includes the families of small pelagic opisthobranchs that have the foot modified into a pair of large parapodia used for swimming. They have transparent shells and bodies so that it is possible to see the large jaws, radula and other organs without dissection. This order is divided into two orders by many workers—the Thecosomata, the shelled forms, and the Gymnosomata, those without shells.

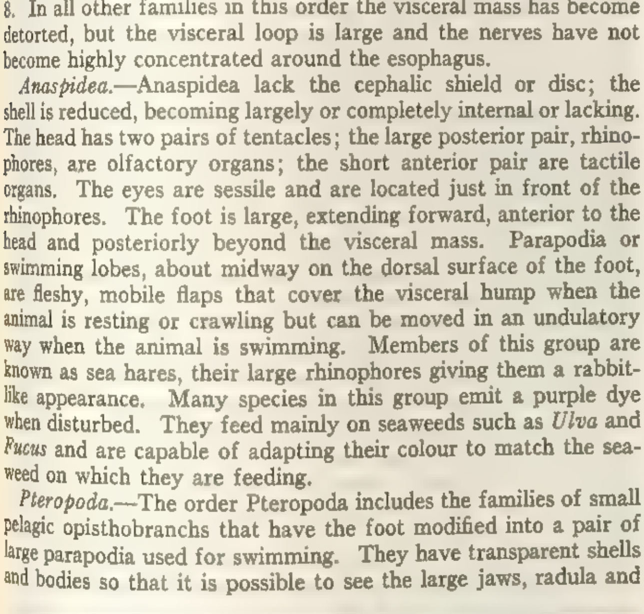

FIG. 12.—SUBCLASS OPISTHOBRANCHIA SHOWING REPRESENTATIVE ORDERS, FAMILIES AND GENERA

The Pteropoda often are referred to as sea butterflies because of their flying motion in the water and their delicate, beautiful colouring. The shelled pteropods, the Thecosomata, are ciliary feeders, collecting microscopic plants and animals by means of cilia on the parapodia or wings and entangling them in mucus from the pallial mucous gland. The muscular gizzard is used to crush diatoms. The Gymnosomata are predators, actively hunting their prey and feeding on minute planktonic animals.

Sacoglossa.—The Sacoglossa is a small order of very specialized opisthobranchs adapted for feeding on the fluid within the cells of algae. They have a radula composed of a single series of strong teeth specialized for piercing and a buccal pump for sucking up the plant juice. Only one tooth is used at a time, and, when it is worn out, it is stored in a sac below the mouth. Members of this order may have thin bulla-like shells or they may be naked and look much like nudibranchs. It is a small but varied group containing five to seven families and probably not more than 50 species. However, since they are small and not easily seen, they really may be more abundant. They are world-wide in distribution, living on seaweeds.

The only known bivalved gastropods (Juliidae) belong to this order. As veliger larvae they have a typical small, coiled shell, but in the adult they are bivalved, the coiled embryonic shell remaining on the left valve. The shells have been known from the fossil record of the Oligocene of Europe. Studies made of the living animal, discovered by S. Kawaguti in 1959, proved that the Juliidae are gastropods rather than bivalves of the class Pelecypoda, as was earlier believed. Species in two genera, *Julia* and *Berthelinia*, have now been found extant. Once it was known that these small and remarkable animals were restricted to feeding on the seaweed *Caulerpa*, workers readily found them in waters off Japan, Australia, Hawaii, Jamaica and the west coast of Mexico.

Acochlidacea.—The order Acochlidacea is a very small group of minute and highly specialized opisthobranchs that live in sand and mud and feed on detritus. They are adapted for burrowing, the anterior end being narrow and extensible. The visceral sac is free from the foot and extends out posteriorly. Much of the body may be covered with spicules that probably aid in burrowing. The shell is lacking in this order as well as the gill and parapodia. (This group was included along with the Notaspidea in the order Aceola by Thiele.) They are probably world-wide in distribution, though little is known about them. They are often found inside minute gastropod shells where they probably go both for protection and to feed on the remains of dead animal matter.

Notaspidea.—The order Notaspidea contains two families of large opisthobranchs, usually with a flat, disclike shell that may sit like an umbrella on the top of the animal (Umbraculidae), may be covered by the mantle or may be absent (Pleurobranchidae). The foot is large and flat, adapted for creeping and adhering to rocks; there are no parapodia. A single large ctenidium or gill is located on the right side in the groove between the mantle and the foot. The tentacles may be small or large and, in pleurobranchs, are fused together, forming a broad veil that extends over the mouth. The rhinophores are usually large. These are bottom-living detritus and plant feeders; they have a broad radula with many rather uniform teeth typical for this type of feeding.

Species in these families are world-wide in distribution in tropical and subtropical seas, a few forms reaching temperate regions. In Australia they are commonly referred to as umbrella shells and side-gilled sea slugs. They may be found from just below the low-tide line out into somewhat deeper water in areas where seaweed is abundant, providing surfaces to which these species usually attach their strings of gelatinous eggs. Although the shells of these forms are not attractive, the animals may be brilliantly coloured and must be seen alive to be appreciated.

Nudibranchia.—This is the largest order of the Opisthobranchia, comprising more than 30 families and containing those forms usually referred to as sea slugs. Nudibranchs are among the most beautiful of all mollusks, though generally they are known only by

the specialists, for most of the species are small. Their beautiful colouring and varied form can be appreciated only when the animal is alive and active, for these soft-bodied mollusks, often with elaborate outgrowths on the dorsal surface, collapse when removed from the water.

Externally they are bilaterally symmetrical; they are shell-less in the adult stage and lack a true gill and mantle cavity. Detorsion is complete in this group, and the nervous system is more highly concentrated in the head region than in other opisthobranchs. The club-shaped rhinophores may be elaborately developed and accessory gills may be present in some forms, while others use the entire body surface for respiration. Dorsal outgrowths (cerata), which may be club-shaped or branching, are common. One group of nudibranchs, the aeolids, feed on coelenterates and store the nematocysts (the stinging cells) of corals in their dorsal cerata; they may serve to protect the animal. Other nudibranchs feed on sponges; the pelagic forms feed on jellyfish and siphonophores.

Nudibranchs are world-wide in distribution, though they are far more abundant in tropical seas. The largest and most beautiful sea slugs are to be found on the Barrier Reef of Australia; one species there reaches 12 in. (30 cm.) in length. They may be found living in tide pools or below low-tide line on rocky shores, among attached seaweed, on coral, hydroids, sponges or barnacles. Some species live only in floating seaweed, such as the sargassum sea slug (*Scyllaea pelagica*), while others, such as the sea lizard (*Glaucus eucharis*), live in swarms in the open sea, where they may form a violet-blue carpet on surface waters.

3. Pulmonata.—The third subclass, the Pulmonata (*pulmo*, "lung"), includes only land and fresh-water species, with the exception of the families Siphonariidae, Oncidiidae, Ellobiidae and Amphibolidae (fig. 13). The gills are lacking and respiration takes place in a pulmonary cavity well supplied with blood vessels and having a contractile orifice. This subclass is often referred to as the land Euthyneura, for most specialists believe they, like the marine Euthyneura, also have undergone detorsion. The nervous system is highly concentrated in the head region.

All pulmonates are hermaphroditic, and in most forms the reproductive system is highly complicated and specialized. Fertilization is internal, and the eggs may be deposited in gelatinous masses or they may have a calcareous shell. The radula is broad, relatively short, with a central tooth and numerous rather similar laterals and marginals. Most species are plant and lichen feeders, though a few, such as members in the Streptaxidae, Haplotrematidae and

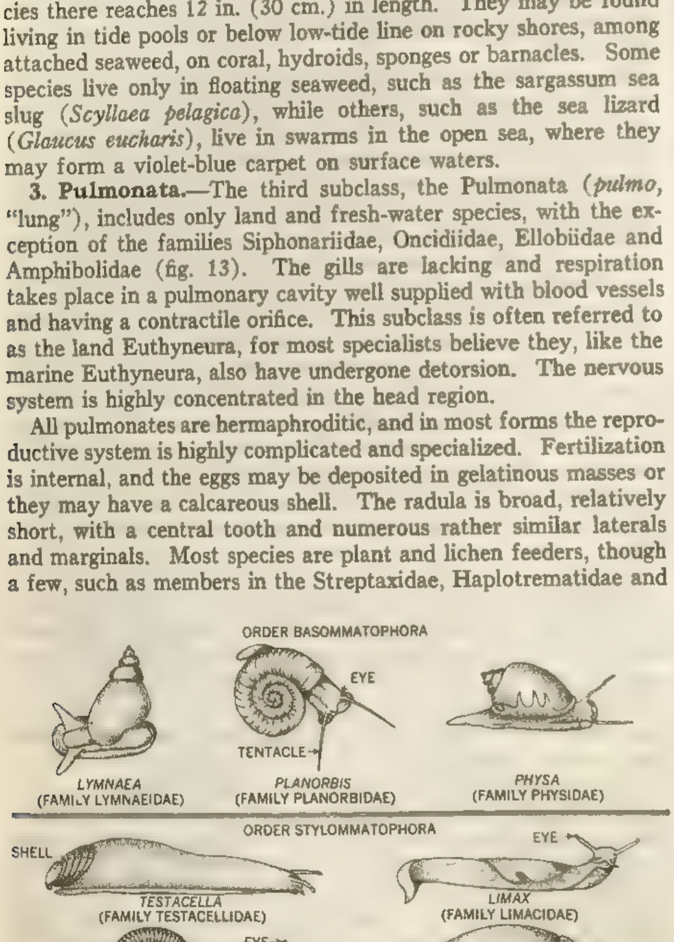

FIG. 13.—SUBCLASS PULMONATA SHOWING REPRESENTATIVE ORDERS, FAMILIES AND GENERA AND CHARACTERISTIC DENTITION

Oleacinidae, are carnivorous. Most families have well-developed spiral shells, though in the Ancyclidae, Siphonariidae, Lancidae and in one genus of the Planorbidae the shells are limpetlike. Some of the land slugs are shell-less, while others have the shell greatly reduced.

The fossil record of the Pulmonata is very limited, for most land and fresh-water snails do not live and die in situations favourable to fossil formation. The best records are from relatively recent loess formations. They are known at least as far back as the Pennsylvanian. The three orders in this subclass are easily recognized and are agreed upon by all workers, though there is some disagreement about the placement of the Systellommatophora, some regarding this group as belonging to the Opisthobranchia.

Systellommatophora.—This is a small order of primitive, sluglike, pulmonate snails that have no mantle cavity and have the lung, nephridial opening and anus at the posterior end of the body. The eye stalks are contractile but cannot be inverted as in the Stylommatophora. They are hermaphroditic and the openings of the male and female systems are separate, as in the Basommatophora. The male opening is on the right side of the head, the female opening farther back on the right side. Three families are included: the Oncidiidae are intertidal but move about and feed only during low tide when they are out of water; the Veronicellidae and Rathouisiidae are land forms restricted to humid areas of the tropics and near tropics. The common Cuban species *Veronicella floridana*, also found in southern Florida, feeds only at night and may be quite destructive in gardens.

Basommatophora.—Members of this order are characterized by having only a single pair of short, broad, noncontractile tentacles, with the eyes at the base. The shell may be extended and spirally coiled, flattened and planospirally coiled or cap-shaped. The openings of the male and female reproductive systems are separate and lie close together on the right side near the eye. This order includes mainly fresh-water species, though there are a few brackish-water and marine forms.

The Ellobiidae are heavy-shelled, spirally coiled marine and brackish-water gastropods often found in salt marshes; the Siphonariidae are limpetlike marine species found on rocky shores and on roots of mangroves. The Physidae and Lymnaeidae include the common thin-shelled, fresh-water snails often referred to as pond snails, though they are also found in streams and large lakes. Although some lymnaeids come to the surface to fill the lung with air, other deep-lake forms are entirely aquatic, filling the pulmonary cavity with water. These two large families are easily distinguished: in the Physidae the aperture is on the left (sinistral) and in the Lymnaeidae on the right (dextral). The Planorbidae have flattened shells, generally coiled in a single plane. The Ancyclidae are limpetlike fresh-water snails. Only the Amphibolidae have an operculum; this is a small family of rather primitive pulmonates found in the upper intertidal salt and brackish-water marshes of Australia and New Zealand.

The reproductive system in the Basommatophora is very much like that of many opisthobranchs; only Ellobiidae (the salt marsh snails) have free-swimming young. In the Amphibolidae and Siphonariidae the eggs are produced in a jellylike mass or in coiled strings similar to those of opisthobranchs, without a separate capsule for each egg. The remainder of the Basommatophora produce the eggs in a jelly mass but each egg has its own capsule and sufficient yolk so that it passes through the trochophore and veliger stages within the capsule, emerging as miniatures of the adult.

Stylommatophora.—Families in the order Stylommatophora contain members characterized by having two pairs of tentacles that are retractile and can be invaginated. The eyes are located at the tip of the large tentacles. The openings of the male and female reproductive systems are united. The shell, which is present in most forms, is helicoid and generally one of three basic forms: lenticular, globose or attenuate. In land slugs the shell is rudimentary and internal or absent.

The reproductive system in the Stylommatophora is the most highly developed in the Mollusca and many groups of land snails have an involved courtship behaviour. The eggs of land snails are generally fewer in number, larger, with more yolk and with a much

better protective covering than is the case in marine and freshwater forms, adaptations to the hazards of living on land. Many land snails that lay their eggs in damp ground have a tough, gelatinous coating around the egg; others lay eggs with calcareous shells; while still others retain the eggs within the body of the parent until they are ready to hatch (Sagdidae).

Most land snails are plant and detritus feeders, though a few are carnivorous, feeding mainly on other snails, snail eggs, worms or insect larvae. Most pulmonate snails belong in this order, which contains about 50 families (many more according to some workers) and perhaps 8,000 species.

See also references under "Snail" in the Index.

Bibliography.—The following list contains only a very small portion of the multitude of books and papers written on this subject; most of them, however, have extensive bibliographies that will lead to greater details on the various groups of gastropods.

SNAKE, common name for reptiles whose most distinctive features—reduction or loss of limbs, reduction or loss of one lung, and lengthening of internal organs—are associated with extreme elongation of the body. Among the smallest is a thread snake of Syria, about the size of a knitting needle; the giants are tropical pythons reported to be more than 30 ft. long. Snakes, suborder Ophidia or Serpentes, are closely related to the lizards, and with them constitute the dominant order of modern scaly-skinned reptiles, the Squamata. They may have originated from some monitorlike lizard stock of which the Bornean *Lanthanotus* may be a unique survivor; fossils identifiable as snakes are known from the Cretaceous Period.

Snakes have always inspired mankind with feelings of fear and revulsion, but also with awe. Their pictorial representations, carved in antlers, are found as early as the Paleolithic Age. Serpents figure prominently in the religion and mythology of all primitive peoples; their worship, still widespread, may be the greatest of all animal cults. The economic importance of snakes is considerable. The major item on the debit side is the mortality arising from snakebites, estimated at more than 30,000 deaths yearly, with the highest incidence in Burma. There are also losses due to predation on domestic and stock animals, and more seriously, destruction of animals that serve as natural controls of injurious insects. These ill effects, however, are offset by the beneficial activities of the rodent-eating snakes. Snakes are also used for food in many countries, and their skins produce ornamental leathers for which there is a demand. The venom has some limited pharmacological applications. To satisfy these demands there have been attempts to "farm" snakes. The various snake parks, mainly associated with the preparation of antivenins, are usually dependent upon captured specimens.

Distribution.—Snakes are cosmopolitan in distribution, with the exception of the Arctic and Antarctic regions, New Zealand, Ireland, and some of the more recent oceanic islands. A few species reach or cross the Arctic circle (*e.g.*, the adder in Europe and a ribbon snake in Canada), but the areas of permanently frozen subsoil limit snake distribution both geographically and topographically. Upper montane limits are 9,800 ft. (3,000 m.) in the European Alps (adder), about 13,000 ft. (4,000 m.) in Mexico (a garter snake and a rattlesnake), and 15,700 ft. (4,800 m.) in the Himalayas (a pit viper). Within these limits snakes occur in almost every kind of environment, arid or humid, subterranean, terrestrial, arboreal, freshwater, and marine, with the greatest numbers being found in the damp tropics.

Characteristic Features.—The following characters, typical of snakes, are also to be found, though seldom in combination together, in various lizards, notably in burrowing snakelike forms such as the Amphisbaenidae.

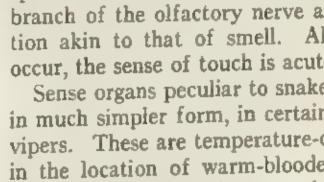
Snakes typically are devoid of limbs, though vestiges of the hind pair occur in a few families. Associated with the attenuated body form are increase in the number of vertebrae and ribs, reduction or suppression of the left lung, staggering of the other paired internal structures, and closure of the front end of the braincase. Although the mouth is narrow, certain anatomical features allow the passage of bulky prey: bones supporting the jaws are reduced in number and are loosely articulated; the rami of the lower jaw are connected by a very elastic ligament; and the glottis is protrusible to permit respiration while the mouth is occluded by prey.

The flexibility and strength of the vertebral column necessary to withstand the stresses set up by the methods of locomotion are ensured by additional articular surfaces between the vertebrae (zygantra and zygosphenes). There are no movable eyelids; the cornea is protected by a fixed transparent scale called the brille. Sight is one of the more important senses in most terrestrial and arboreal snakes; probably there is colour vision. There is no external ear or tympanum and the middle-ear bone abuts laterally against the quadrate bone of the skull so that vibrations of the substratum are picked up; only low-frequency sound waves, between 100 and 700 cycles, are perceived. The tongue, elongate and retractile into a basal sheath, has a forked tip whose points can be inserted into two depressions on the roof of the mouth—the openings of the chemoreceptor organ of Jacobson.

There are adaptive modifications associated with the different environments. For example, in burrowing forms the skull bones are more firmly articulated, eyes are smaller and may be sunken, and scales are close fitting and highly polished. Nocturnal and twilight-active species have elliptically contractile pupils. A few arboreal species may have binocular vision; this is achieved, not as in other vertebrates by a forward rotation of the orbits but by the pupils being long, horizontal slits situated excentrically near the anterior margins of the lateral orbits.

The senses of smell and taste are supplemented by the tongue operating in conjunction with Jacobson's organ. The repeated protrusion and flickering of the tongue, so characteristic of snakes, is a chemical sampling of the environment. Airborne particles adhering to the tips of the tongue are transferred to the sensory epithelium lining Jacobson's organ; this organ is innervated by a branch of the olfactory nerve and presumably produces a sensation akin to that of smell. Although no special tactile organs occur, the sense of touch is acute.

Sense organs peculiar to snakes are found in the pit vipers and, in much simpler form, in certain boids, and perhaps also in some vipers. These are temperature-differential receptors and are used in the location of warm-blooded prey in darkness. In the pit vipers, the organ lies between the eye and the nostril, and consists of two chambers separated by a diaphragm. One of the chambers is wide open to the exterior, exposing the diaphragm, which is richly supplied with nerves. The diaphragm is very sensitive to infrared radiation: an object can be accurately located when its heat radiation produces on the membrane a temperature only 0.36° F higher than that of the surrounding air. In the boas the heat-receptors are a series of simple pits along the lips and the suspected receptors of the pit vipers are sacs associated with the nostrils.



FROM J. Z. YOUNG, "THE LIFE OF VERTEBRATES," AFTER GADOW, 1950. THE CLARENDON PRESS, OXFORD

FIG. 1.—HEAD OF PIT VIPER, SHOWING POISON AND SENSE MECHANISMS

There are three main types of dentition in venomous snakes. In the Opisthoglypha (many Colubridae), the fangs, one to three in number, lie at the posterior end of the upper jaw; they

are enlarged teeth with a lateral groove that acts as a channel for the venom. In the other two types, the fangs lie at the front of the upper jaw and the channel for the venom is an enclosed canal opening at the fang tip. In the Proteroglypha (Elapidae, Hydrophidae) the bone bearing the fangs is relatively long and immovable; it often bears some simple teeth behind the fangs. In the third type, the Solenoglypha (Viperidae), there are no teeth immediately behind the fangs, and the short bones on which the fangs are inserted are rotatable about their transverse axis through about 90°; this allows the fangs to be folded down flat, tips directed posteriorly, when the mouth is closed. The harmless colubrine snakes with solid conical teeth are sometimes called the Aglypha.

FIG. 2.—SKULLS OF (LEFT) NONPOISONOUS AND (RIGHT) POISONOUS SNAKES

(Left) Royal python skull showing teeth adapted for seizing and swallowing prey; (right) Gaboon viper skull showing fangs

Salivary glands are present, two of which in certain snakes are modified into venom sacs. Food is well coated with saliva and is then smoothly worked into the esophagus by muscular action and the gripping power of the teeth (see *Feeding*, below). The esophagus bears longitudinal folds that permit expansion, another adaptation to allow passage of large prey. Products of digestion pass into the slightly coiled small intestine, while indigestible matter are regurgitated. A valve forms the junction of the small and large intestines; at this point is a primitive colic caecum or pouch. The short, straight large intestine opens into the cloaca, where sex products of the paired testes and the wastes of the paired kidneys also empty; there is no urinary bladder.

Locomotion.—Locomotion is accomplished by several methods, here broken down into four main types: serpentine (undulatory), rectilinear (straight crawling), thrust creeping and sidewinding.

The commonest means of locomotion is by serpentine movement, in which sinuous lateral undulations that originate anteriorly travel toward the tail; the pressure of these waves against objects produces a thrust that drives the animal forward.

Terrestrial and arboreal snakes often exhibit rectilinear locomotion. The belly has a series of transversely enlarged overlapping plates that provide for forward movement in a straight line. When some of the muscles of the body wall are contracted and relaxed, the ventral plates act like a series of ratchets. Their anterior edges, being overlapped by the preceding plate, slide freely forward even over a rough surface, but any backward movement is prevented because the projecting posterior edges catch on the least irregularities. In consequence, contractions of the muscles produce a series of small thrusts forward. Since increased length increases efficiency for both undulatory and rectilinear locomotion, slender species are generally swifter and more active than thickset ones. In completely aquatic forms, swimming is by lateral undulations and there are no enlarged ventral scales; efficiency is increased by lateral compression of the body, and, particularly, of the tail, which is paddle-shaped in the sea snakes.

Since serpentine movement is not possible in the confines of a narrow burrow, there is provision for thrust creeping by means of short, blunt, muscular tails, often armed with tubercular or spinose scales. The body is first thrown into a number of sinuous curves of the restricted amplitude allowed by the burrow and then straightened while the tail is held fast by firm pressure against the sides of the burrow.

One of the most extraordinary means of snake progression, well suited for traveling over loose sand, is sidewinding. The most notable example is found in the North American Desert, or horned, rattlesnake (*Crotalus cerastes*), often called sidewinder. This snake repeatedly throws a loop of its body forward and to one side, leaving a series of more or less parallel oblique tracks in the sand.

Feeding.—Snakes are insectivorous or carnivorous, and their prey is swallowed whole. The teeth, thornlike, with their tips recurved backward, are arranged in single rows along the jaws with, frequently, two additional rows on the roof of the mouth. The prey, which in most instances must be alive to interest a snake, is seized in the mouth by a rapid strike; then the process of overpowering and swallowing begins. Nonvenomous species swallow prey alive if it is small. A few species can subdue large and struggling prey by constriction; *i.e.*, coils of the snake's body are thrown around it and gradually tightened. The prey is worked around until its head is in the snake's mouth and swallowing begins.

Due to the loose articulations of the bones supporting the jaws and the elastic ligament between the halves of the lower jaw, the potential gape of the mouth is enormous. The hooked teeth permit food to be pushed easily into the mouth but not easily withdrawn. While the teeth of one side of the mouth are engaged and act as a fulcrum, the jaws of the opposite side are pushed forward for a short distance; then their teeth in turn act as a fulcrum, and so on. During this process teeth are frequently broken off, but there is a series of replacement teeth in different stages of development, and a lost tooth is quickly replaced from this successional series; even when no injury occurs, the functional teeth are periodically replaced, alternate teeth at a time. Venomous snakes usually release their victim immediately after injecting venom with the first bite. The prey is then followed either by sight or by scent, and is eaten only when the poison has taken effect.

The majority of snakes have restricted food preferences, which may involve some physiological or morphological adaptations. For instance, the American king snakes, though themselves nonvenomous, attack and eat venomous snakes with impunity. The African *Lycophidion* preys largely on hard-scaled lizards (skinks) and has enlarged caninelike teeth on both jaws. Some snakes (Dasypeltinae) subsist almost exclusively on birds' eggs and the thirst snakes (Dipsadinae) eat snails. The egg-eating snakes have a reduced, almost functionless, dentition but a mouth so distensible that a large egg can be swallowed whole. Their cervical vertebrae, however, have enlarged lower processes (hypapophyses), some of which perforate the esophagus to form a median row of toothlike structures on which the egg is crushed; the contents of the egg pass on into the stomach but the shell is regurgitated. The Dipsadinae deal with their hard-shelled prey differently. Here, although the upper jaw teeth are reduced in number, the lower jaw, with enlarged teeth in front, can be swung forward a long way; it is thrust into the shell, its teeth engaged in the soft tissues, and then retracted, drawing the snail out.

Life History.—Snakes are essentially nongregarious, though congregations of individuals may be attracted by favourable environmental conditions. The burrows of other animals may be attractive for shelter (*e.g.*, for hibernation) or for the food they offer (*e.g.*, termite galleries); or many females may gather at the same spot for egg laying. There are, however, no known instances of social organization or community life. In consequence, except

where mass hibernation is the rule (*e.g.*, among rattlesnakes) and mating occurs with the spring awakening, the meeting of the sexes for reproduction may not be easy. Females are probably located by scent, which in some instances arises from an epidermal secretion but in others from the secretion of a pair of saclike glands that open just inside the cloaca. There is evidence that certain snakes (*e.g.*, *Coluber*, *Naja*) mate with only one partner in a season, and in others the female is able to store viable sperm, sometimes for as long as five years (*Leptoderia annulata*), as a safeguard against failure to find a mate.

Courtship usually consists of pushing and weaving movements initiated by the male, during which the chin is rubbed against the female's neck. In a few instances, for example, in the European Aesculapian snake, there is a nuptial dance that may last for more than an hour; in this species there is mutual pursuit, the two snakes coiling together, each raising the head and neck and the two forming a lyre-shaped figure. Behaviour similar to this occurs in many other snakes (adders, rattlesnakes, cobras, etc.), but in these instances the participants are both males and the "dance" appears to be a ritual displav of aggression.

Fertilization is internal. The male terminates courtship by inserting one of a pair of intromittent organs, collectively called hemipenes, into the cloaca of the female; sperm passes along a groove on the hemipenis, enters the cloaca, and travels up the oviduct where it fertilizes the eggs. At rest, each hemipenis lies in a fold of the skin at the base of the tail, near the cloaca. Diminutive hemipenes of the female are of doubtful function. (*See* also REPTILE: *Urogenital System* and *Reproduction and Development*.)

Most snakes lay elongate eggs with a parchmentlike shell; they are usually buried in warm, damp soil. In some groups ovoviviparity, or hatching of eggs in the female's body, is the rule; in a few instances there is true viviparity, the developing young being nourished through a placenta. The number of eggs or young varies from one or two to more than a hundred, and the incubation or gestation period depends upon the prevailing temperature. In some ovoviviparous species in cold climates (*e.g.*, the adder), the young may not be born until the summer following that of conception. Few snakes exhibit parental care. The king cobra, or hamadryad, scoops together a pile of detritus in which the eggs are laid and the female coils herself upon it. Some other cobras, and also some kraits and pythons, guard their eggs. Pythons coil around the clutch; it has been claimed that the python can raise its body temperature to assist incubation. Growth is greatest in the earliest stages but probably never ceases entirely. Associated with growth is sloughing, whereby the skin is cast off and renewed periodically, every one to three months on the average; beginning at the lips, the old skin is turned back on itself, inside out, in one piece.

Although a few snakes have hornlike processes on the snout or above the eyes, these do not appear to be weapons. The

FIG. 4.—SHEDDING OF SKIN BY RED-BELLIED WATER SNAKE (NATRIX ERYTHROGASTER ERYTHROGASTER)

teeth and the venom apparatus are primarily offensive, in connection with the acquisition of food, and only secondarily defensive, except in the cases of the black-necked and spitting cobras; these cobras have the ability to eject a highly irritating venom into the eyes of an enemy. Other defensive devices include pungent glandular secretions. Despite all these methods, defense is achieved, in the main, by behaviour. Explosive hissing and threats of biting are common practices, often accompanied by intimidatory posturing such as inflation of the neck or the spreading of a "hood," as in some cobras. Shamming dead and rolling into a compact ball with the head concealed in the middle are also common defense measures. The North American rubber boa (*Charina*) rolls into a ball and also directs attention to a nonvital part by waving its tail in the air. Many other snakes divert attention even more effectively; the tail is often distinctively coloured and makes stabbing movements like a striking head. A few snakes, like the desert-dwelling vipers *Aspis* and *Echis*, give audible warning by rubbing together certain scales on their flanks or, like the rattlesnakes, by means of a rattle at the tip of the tail.

Venom.—Venom is secreted by venom sacs, situated laterally behind the eyes and connected by ducts to the base of the fangs. The venom contains certain poisonous proteins present in varying amounts according to the species of snake. The poisons belong to two principal types: histolytic substances that destroy the body tissues, including blood cells and the lining of blood vessels, and neurotoxins, which attack the nervous system and cause paralysis, especially of the respiratory apparatus. When neurotoxins predominate, paralysis, general prostration, and difficulty in breathing are the most dangerous effects; if the victim survives this stage, recovery is rapid and there are few serious local symptoms at the bite. When the other substances predominate, there is no paralysis, but there are severe constitutional symptoms, with vomiting and prostration, local and general hemorrhage, and much painful swelling of the bitten parts, which may become gangrenous.

Since the poison apparatus is primitively and primarily a device for killing food, the toxicity of the venom is related to the normal prey; for example, the venom of the crab-eating, oriental *Fordonia* is highly toxic to crustaceans but not to fish or amphibians, and that of the fish-eating sea snakes is toxic to fish but much less so to warm-blooded animals. In the aglyphous, "harmless" Colubridae, which lack any venom canals on their teeth, the saliva may be toxic, at least to the animals on which they prey.

First aid in cases of snakebite on the extremities consists of the immediate application of a light ligature, on the side of the wound closest to the body, and suction of the wound. Exertion and excitement should be avoided to prevent an increase of the pulse rate; for the same reason, stimulants should be avoided. The application to the wound of substances such as potassium permanganate is likely to be harmful rather than helpful.

Antivenins, manufactured in many countries, are prepared by the immunization of animals against particular snake venoms. The immunized serum is effective only against the venom with which it was prepared. To ensure treatment with an appropriate antivenin, it is therefore important that the snake be identified. It is highly desirable that antivenins be administered under medical supervision since there may be allergic reactions. In cases where the main toxin destroys blood cells, blood transfusions may be indicated. (*See* also VENOM.)

Classification and Survey.—Snakes number about 3,000 extant species. The generally recognized families may be grouped as follows, under a conservative taxonomic system.

Typhlopidae (*Blind Snakes*).—Small, harmless, burrowing snakes with bluntly rounded heads and tails, without enlarged ventral scutes and usually with vestiges of pelvic bones; teeth are present on the upper jaw, but absent on the lower; eyes are minute. Blind snakes occur in most tropical countries. Their food consists of small invertebrates.

Anomalepidae.—A small family of South and Central American snakes that resembles the blind snakes in appearance and habits but lacks any vestiges of hind limbs or pelvis. They have teeth in the upper jaw and a single, small tooth in the lower jaw. They are unique among snakes in possessing, in common with lizards, a jugal bone bordering the orbit of the eye.

Leptotyphlopidae (*Thread Snakes*).—Although superficially similar to the preceding, thread snakes have teeth only on the lower jaw. They inhabit Africa, southwestern Asia, and America. Most species are uniformly brown or black, but the commonest species in tropical America, *Leptotyphlops albifrons*, has white patches on the head and tip of the tail, a pattern which enhances the similarity of these extremities to the possible confusion of an aggressor. Some species have the unique habit of sucking out the contents of termites' abdomens.

Aniliidae.—This family of harmless burrowing snakes of South America and southeastern Asia is characterized by teeth on both upper and lower jaws, clawlike vestiges of hind limbs, and slightly enlarged ventral scales. They are larger than most burrowing snakes, reaching two and one-half to three feet. Their food consists principally of other snakes and eels. The South American *Anilius scytale* resembles some coral snakes in its colour pattern of bright coral red with black rings. The Indo-Malayan *Cylindrophis rufus* is usually crossbanded in brown or black and white, but the underside of the tail is vermilion; if the snake is disturbed it raises the tail aloft, showing the bright colour, and makes darting movements with it. The same tail colour and reactions are characteristic of the venomous elapid snake *Maticora intestinalis*, which inhabits the same region.

Uropeltidae (*Shield Tails*).—These harmless burrowing snakes, similar to the preceding but without vestiges of hind limbs, have an enlarged spiny or rugose shield on the tip of the tail. Inhabiting Ceylon and southern India, they burrow in damp, forest earth, and feed mainly on earthworms.

Xenopeltidae (*Sunbeam Snakes*).—The unique species, *Xenopeltis unicolor*, of southeastern Asia is a harmless, handsome snake, black or chocolate brown in colour with highly iridescent scales; there are no vestiges of limbs, but a left lung half the size of the right is present. It is cryptozoic and feeds on other snakes, small rodents, and frogs.

Boidae (*Boas, Pythons, and Wood Snakes*).—This group of nonvenomous snakes, with a lineage extending back to at least Cretaceous times, is characterized by the retention of vestiges of hind limbs and, usually, of two lungs; teeth are present on both upper and lower jaws; and there are enlarged ventral scales. Four subfamilies may be recognized, the two largest being the circumtropical boas (Boinae) and the Old World pythons (Pythoninae). The boas mostly bear living young. The larger species are nearly all arboreal. The biggest of them, the South American anaconda, is arboreal and aquatic. The smallest boas, seldom exceeding three feet, are the sand boas (*Eryx*) of the semi-desert regions of northern Africa and southwestern Asia. The egg-laying pythons inhabit the tropics from western Africa to northern Australia, Melanesia, and Polynesia. The largest species are the Oriental reticulate python and the African rock python, both of which may exceed 30 ft. (9 m.) in length. *Loxocemus*, a Central American form, was at one time thought to be a python (the only one in the New World); but it has proved to be related in several points to the sunbeam snakes and is allotted an isolated position in the family as the sole member of the subfamily Loxoceminae. The Central American and Antillean wood snakes, at one time regarded as boas, are now known to have only one lung and to have a few unique features; they are placed in another subfamily, the Tropidophiinae. (*See* also BOA; PYTHON.)

FIG. 5.—CERTAIN ANATOMICAL CHARACTERISTICS OF VARIOUS FAMILIES OF SNAKES

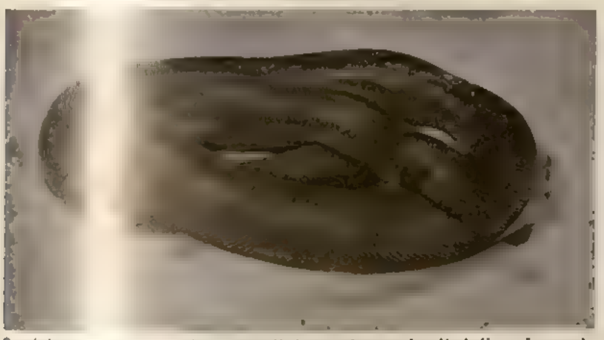
Bolyeridae.—This family of two genera, *Bolyeria* and *Casarea*, each with one species, occurs only on a tiny island, Round Island in the Indian Ocean; these and extinct remains of a third species found on nearby Mauritius, have some boalike features. But they have no vestiges of hind limbs or pelvis, their left lung is almost vestigial, they have some peculiarities of the vertebral column and the unique feature of a transversely divided upper jawbone. They may represent a little group that has been isolated since the Indian Ocean islands were formed, probably in Eocene times.

Acrochordidae (*Wart Snakes*).—This family contains only a single genus with two species. These are harmless aquatic snakes that live in the fresh waters and estuaries of the Indo-Australian region. They resemble the harmless members of the Colubridae (below) in lacking vestiges of limbs and in having one lung; but they have no enlarged ventral plates and are peculiar in having a very loose baggy skin with small, wartlike granules instead of overlapping scales. Their eyes are tiny, and the air passage from the nostrils can be closed to exclude water by a flap on the roof of the mouth. Sluggish in disposition and almost helpless if removed from the water, they have a diet consisting exclusively of fish. They produce large litters of young, up to more than 30.

Colubridae.—This family contains the great majority of typical snakes in which there is neither a left lung nor vestiges of limbs; generally the ventral scales are enlarged and the head is covered with relatively few enlarged plates. Teeth are present on both jaws, and the dentition is aglyphous or opisthoglyphous, those with the former condition being harmless to man. The opisthoglyphs are technically venomous, but the small size and position of the

Reticulated pyth… *…hon reticulatus*), one of the largest of all snakes, may reach a length of more than 30 ft. Found in s… …east Asia and the Philippines

Diamond snake or carpet python (*Morelia argus*) of Australia and New Guinea



Sand boa (… *…yx johni*), a small burrowing snake that lives in sandy regions fro… …orth and central Africa to India and central Asia

White Indian python (*Python molurus*), a rare colour freak, not albino, caused by domination of white pigment cells over those of normal coloration

Boa constrictor (*Constrictor constrictor*), widely distributed in South America and found north, along the coasts of Mexico, almost to the U.S. border

Emerald boa (*Boa canina*), an arboreal snake found in the tropical jungles of South America

PYTHONS AND BOAS

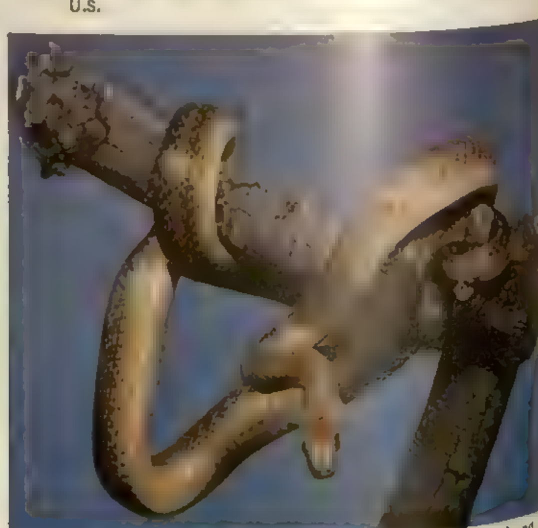
Eastern hognose snakes (*Heterodon platyrhinos*), showing two of the several colour variations that are characteristic of this species. Found in sandy areas of most of the eastern and central U.S.

Yellow rat, or chicken, snake (*E[illegible]he obsoleta quadrivittata*), an arboreal species of the [illegible]th Atlantic coastal U.S.

Texas rat snake (*Elaphe obsoleta lindheimeri*), found in Texas and western Louisiana. Like most other *obsoleta* varieties, it is a large snake and may reach a length of 7 ft.

California king snake (*Lamp[illegible] getulus californiae*) one of many *Lampropeltis* spec[illegible] dely distributed in the U.S.

Red milk snake (*Lampropeltis doliata syspila*). Banded pattern of the harmless milk snakes, or king snakes, is similar to that of some of the venomous coral snakes (Elapidae). Central U.S.



Aesculapian snake (*Elaphe longissima*), a chicken snake found in Europe and Asia Minor

KING, RAT AND HOGNOSE SNAKES

PHOTOGRAPHS, (TOP LEFT, TOP RIGHT, CENTRE LEFT, BOTTOM LEFT) JOHN H. GERARD, (CENTRE RIGHT) WILLIS PETERSON, (BOTTOM RIGHT) JOHN MARKHAM

Eastern yellow-be racer (*Coluber constrictor flaviventris*), an extremely fast-moving, smooth snake found chie Middle West, north of the Ohio valley to the Great Lakes

Rough green snake (*Opheodrys aestivus*), a long, slim arboreal species seen in south central and Atlantic coastal states

Texas long-nosed (*Rhinocheilus lecontei tessellatus*), a speckled, burrowing snake found in arid regions of the reme southwest and northern Mexico

Western worm snake (*Carphophis amoenus vermis*), a small terrestrial snake usually found hidden beneath moist foliage, rocks or ogs

Sonora gopher snake (*Pituophis catenifer affinis*), a large western bull snake known for the loud hissing it makes when attacked or frightened

Western ribbon snake (*Thamnophis sauritus proximus*), a slender garter snake found in most of the middle western states west of the Mississippi river

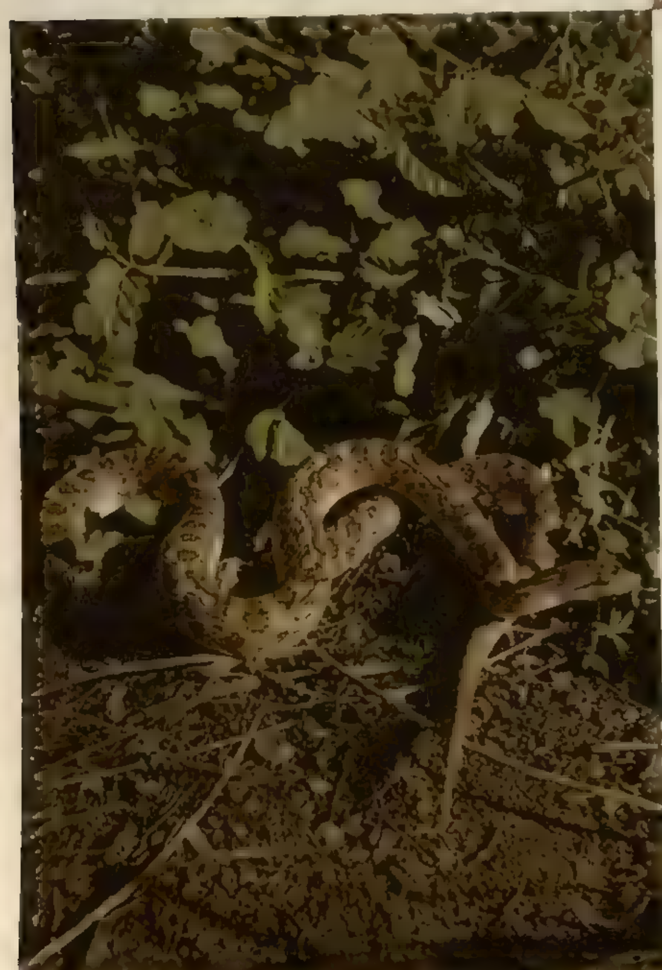
Eastern garter snake (*Thamnophis sirtalis sirtalis*), a very common snake of the entire eastern half of the U.S. and southeastern Canada

COLUBRIDS: HARMLESS SNAKES OF THE U.S.

PHOTOGRAPHS, JOHN H. GERARD EXCEPT (CENTRE RIGHT) CY LA TOUR

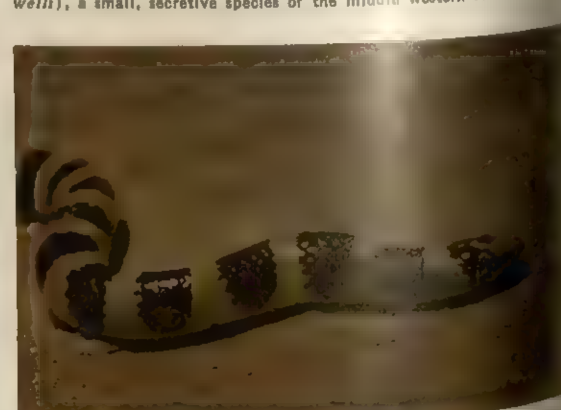
Sonora king snake (*Lampropeltis getulus splendida*), a largely nocturnal species found in the southwest and north central Mexico. It constricts its prey, often other snakes

Speckled king snake (*Lampropeltis getulus holbrooki*), another of the snake-eating snakes. Found in the prairie and south central states



Glossy snake (*Arizona elegans*), a burrowing snake usually found in sandy areas of the southwest and northern Mexico

Northern black-headed, or flat-headed, snake (*Tantilla gracilis ha[illegible]welli*), a small, secretive species of the middle western states

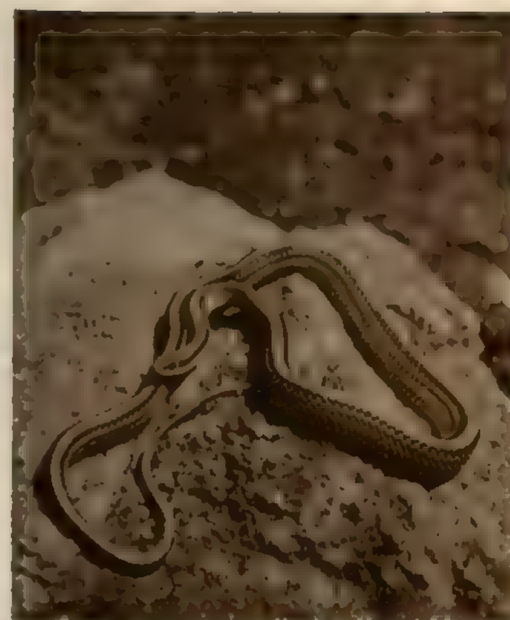


Banded sand snake (*Chilomeniscus cinctus*), a small snake whose [illegible] is adapted for rapid burrowing into sand. Found chiefly in Arizona and Baja California

COLUBRID SNAKES OF THE U.S.

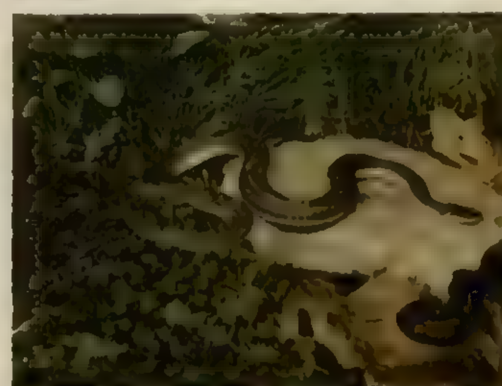
PHOTOGRAPHS, (TOP LEFT, CENTRE RIGHT) JOHN H. GERARD, (TOP RIGHT) JOHN MARKHAM, (BOTTOM LEFT) WILLIS PETERSON, (BOTTOM RIGHT) HYMEN MARX

Western ringneck snake (*Diadophis amabilis*) in its defense posture, coiled with the underside of its tail exposed. Found chiefly on the Pacific coast

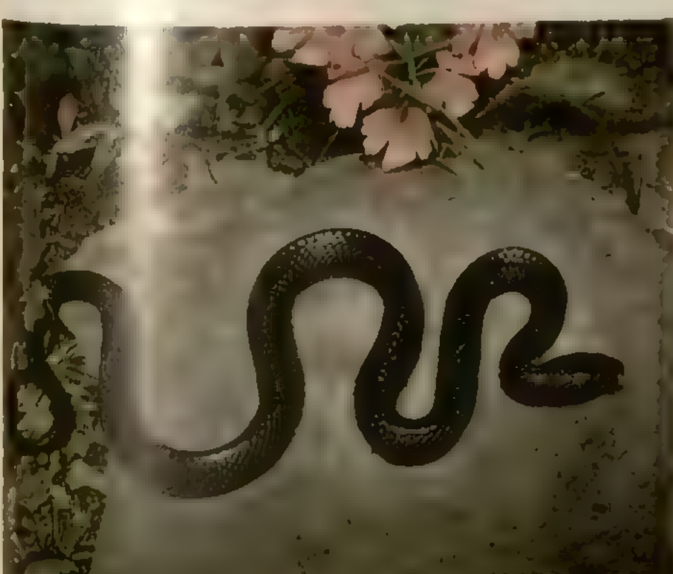


Texas patch-nosed snake (*Salvadora lineata*), a slender species found most often in rocky terrain in northern Mexico, Texas and Oklahoma

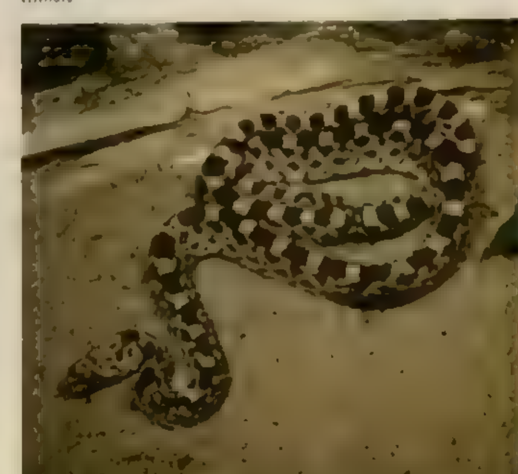
Pacific gopher snake (*Pituophis catenifer catenifer*), a constricting bull snake found on the west coast



Graham's water snake (*Natrix grahami*), found in streams and quiet water west of the Mississippi river to Texas and north to Illinois



Eastern indigo snake (*Drymarchon corais couperi*), a relative of the racers, may reach a length of about 8 ft. Found chiefly in Florida, Georgia and Alabama



Bull snake (*Pituophis melanoleucus sayi*), a large prairie dwelling species that will strike when alarmed but is not dangerous to man

HARMLESS SNAKES OF THE U.S.

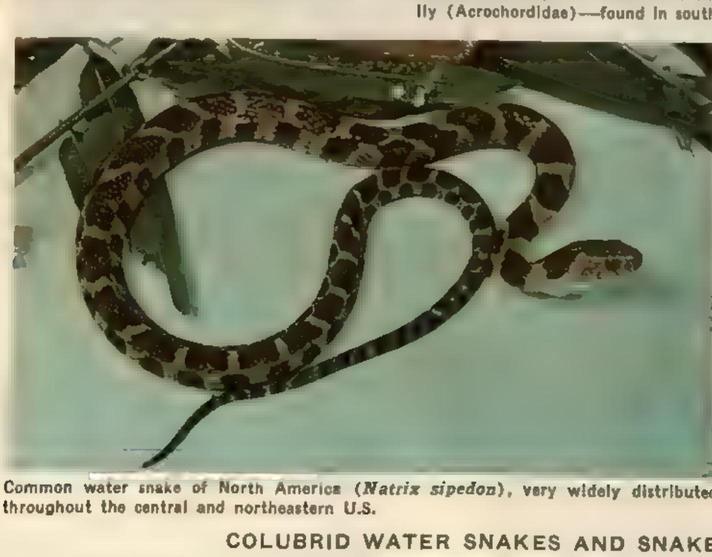
PHOTOGRAPHS, (TOP LEFT) NATHAN W. COHEN, (TOP RIGHT) WILLIS PETERSON, (OTHERS) JOHN H. GERARD

Mangrove snake (*Boiga dendrophilia*), a rear-fanged arboreal species found in tropical Asia

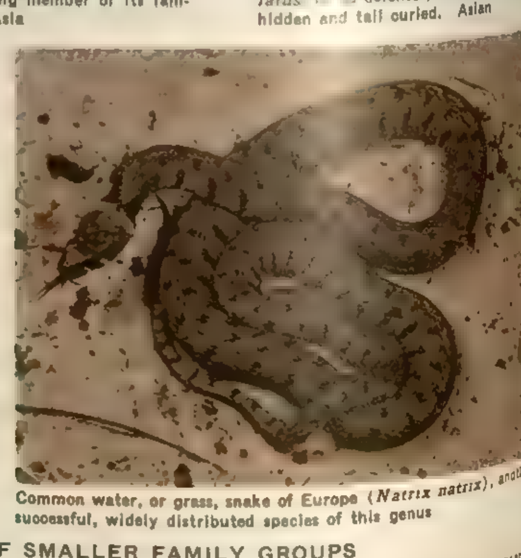
Blunt-headed tree snake (*Imantodes cenchoa*), native to Central and South America

Elephant trunk, or wart, snake (*Acrochordus javanicus*), a loose-skinned aquatic snake—the only living member of its family (Acrochordidae)—found in southeast Asia

An ar[illegible]ake, *Cylindrophis maculatus* [illegible] defense position w th head hidden and tail curled. Asian



Common water snake of North America (*Natrix sipedon*), very widely distributed throughout the central and northeastern U.S.



Common water, or grass, snake of Europe (*Natrix natrix*), another successful, widely distributed species of this genus

fangs make it difficult for them to inflict a dangerous bite on large objects. The larger species, however, can be dangerous, especially the African boomslang, whose venom is hemolytic, like that of the vipers. Several subfamilies can be recognized, though their limits and interrelationships are far from clear.

The Dipsadinae are aglyphous arboreal forms with a specialized diet of mollusks. These snakes lack the groove beneath the chin, present in most other colubrids and a part of the mechanism permitting the halves of the lower jaw to be widely separated. The group is confined to southeastern Asia (*Amblycephalus, Haplopeltura*) and to tropical America (*Dipsas* and allies).

The Homalopsinae, aquatic snakes from the fresh or saline waters of the same region as the Acrochordidae, differ from the latter in being opisthoglyphous, in closing the nasal passages by valvular nostrils, and in having larger imbricating scales of which those on the belly are slightly enlarged.

The Dasypeltinae comprise the egg-eating snakes of Africa (*Dasypeltis*) and northern India (*Elachistodon*), terrestrial snakes with enlarged ventral plates. *Elachistodon* is opisthoglyphous and *Dasypeltis*, aglyphous.

The Colubrinae are snakes with either aglyphous or opisthoglyphous dentition. This large subfamily (often given family rank as the Colubridae) is cosmopolitan in distribution, though poorly represented in Australia. There are many subaquatic forms, generally subsisting on fish and frogs; among them is the cosmopolitan genus *Natrix*, with such species as the European grass snake (*N. natrix*), the Indian keel back (*N. piscator*), and the North American common water snake (*N. sipedon*). Terrestrial forms prey mostly on small mammals, lizards, toads, and birds. Among the better-known forms are the chicken snakes, racers, and rat snakes (*Elaphe* and *Coluber*) of Europe and North America; the Indian rat snakes (*Ptyas*); the African house snakes (*Boaedon*); and the European smooth snake (*Coronella*), the rarest of the three indigenous snakes of Britain. The ophiophagous habits of American king snakes have been mentioned, but this genus, *Lampropeltis*, is noteworthy for another reason: some species, with a pattern of broad red bands edged with black and separated by yellow or buff interspaces, mimic the venomous coral snake.

Arboreal forms, many of which are opisthoglyphous, prey mostly on birds and lizards. Often they are greatly elongate and slender; many are protectively coloured green and brown. Some, such as the Indian green whipsnake (*Dryophis nasutus*) and the Malagasy *Langaha*, have leaflike dermal appendages on the tips of their snouts. Other well-known arboreal species are the dangerous boomslang (*Dispholidus typus*) and the Indian flying snake (*Chrysopelea ornata*). The latter is a handsome black, yellow-spotted snake, with a series of markings like red-centred, yellow flowers along its back; it can slip from a high branch, with its ribs pushed outward to produce a flat or concave lower surface, and execute a steep glide to earth.

Terrestrial genera are represented in Europe by *Malpolon*, the largest snake of that continent. In tropical America is the polymorphic *Erythrolamprus aesculapii*, some of whose many colour varieties mimic coral snakes. In Africa are numerous forms including the ubiquitous sand snakes (*Psammophis*). Some burrowing forms, like *Apostolepis* in South America and *Chilorhinophis* in eastern Africa, exhibit deflective coloration; the head and stumpy tail are alike in shape and colour, both being black with lighter dots.

Elapidae.—This family comprises snakes with fixed poison fangs at the front of the upper jaw, with enlarged ventral plates, and the tail not flattened. All elapids are venomous, the larger ones dangerously so; the venom is usually neurotoxic. They include the cobras (*Naja*) of southwest Asia and Africa; king cobra (*Ophiophagus*), the biggest venomous snake; spitting cobras (*Hemachatus*) and mambas (*Dendroaspis*) of Africa; Asiatic kraits (*Bungarus*); American coral snakes (*Micrurus* and allies); and several Australian genera. The Australian elapids constitute three-quarters of all the terrestrial snakes on that continent, the more important being the taipan (*Oxyuranus*), black snake (*Pseudechis*), tiger snake (*Notechis*), Australian copperhead (*Denisonia*), and death adder (*Acanthophis*). (*See* also COBRA.)

Hydrophidae (*Sea Snakes*).—This is a family of marine snakes that resemble the Elapidae in dentition and most other characters, but lack obvious ventral shields and have vertically flattened, paddlelike tails. Other modifications associated with a completely aquatic life are valvular nostrils and a reduction in the length of the tongue. In connection with their saltwater habitat, sea snakes have nasal glands believed to excrete excess salt. The majority of the species inhabit the littoral seas from the Persian Gulf to southeastern Japan southward to northern Australia and eastward to Samoa. Only one species, *Pelamis platurus*, is truly pelagic, ranging from coast to coast across the Indian and Pacific oceans. Although a few species may attain a length of about 8 ft. (2 m.), the majority are only 3 or 4 ft. (0.9 to 1 m.) long. The usual colours are browns or grays, with blackish crossbars, but *Pelamis* has a uniform brown or black back sharply delimited from a bright yellow belly.

There are two subfamilies, the Hydrophinae, which bear living young and are completely independent of the land, and the Laticaudinae, which lay eggs above the high-water mark.

Viperidae (*Vipers and Pit Vipers*).—These snakes have their fangs set on a rotatable bone (maxilla) that bears no other teeth. There are well-developed, enlarged ventral shields, but the head normally lacks the enlarged plates of the Colubridae and some other families. The venom is usually strongly histolytic.

Viperids are absent from the Papuan, Australian, and Polynesian areas but are widespread elsewhere. Two subfamilies may be recognized; the pit vipers (Crotalinae), from the Americas and across Asia to eastern Europe, and the true vipers (Viperinae), from Europe, Africa, and Asia. Both groups are often given family rank, the pit vipers then being separated as the Crotalidae.

Among the better-known viperine genera are *Vipera*, *Bitis*, *Atheris*, and *Cerastes*. In the first mentioned are such species as the adder (*V. berus*) and asp viper (*V. aspis*) of Europe, and the Indo-Malayan Russell's viper (*V. russelli*). The larger species of the African *Bitis* are the puff adder (*B. lachesis*), the Gaboon viper (*B. gabonica*), and the rhinoceros viper (*B. nasicornis*). *Atheris* is an arboreal African genus, often coloured a velvety emerald green, with a prehensile tail.

Cerastes includes the desert horned asp of Egypt and neighbouring countries, which has a thornlike spine above each eye. The crotalines include the moccasins and copperheads of North America and related species in Asia (*Agkistrodon*); the fer-de-lance group (*Trimeresurus* or *Bothrops*), also American and Asiatic; the notorious bushmaster (*Lachesis*); and many species of rattlesnakes (*Crotalus, Sistrurus*) in the Americas. (*See* also RATTLESNAKE; VIPER.)

See REPTILE; *see* also references under "Snake" in the Index.

SNAKEBIRD (DARTER OR ANHINGA), a bird belonging to the same order as the cormorant (*q.v.*), which it resembles in outward form and in habits. The snakebirds, however, are slenderer and have an elongated neck and tail. The pointed bill has its edges beset with backwardly directed "teeth." There is only one genus of snakebirds, *Anhinga*, with four species occurring (one each) in the Americas, Africa, southern Asia, and Australia. The male of the American species, *A. anhinga*, often called the water turkey, has black plumage, glossed with green, with a white line on the neck; the bare skin of the head is both green and orange, and there are white stripes and patches on the wings and tail. The bird haunts large rivers and lakes, frequently perching on overhanging branches. It feeds on fish, which it chases and spears

with its daggerlike bill; its agility under water is amazing. It often swims with only its head above water. The bird has been observed to play at catch with small twigs. The nest, built in a tree close to the water, is a large structure of sticks. The four eggs have white, chalky shells.

All four species are characterized by their serpentine necks; the vertebrae articulate in such a way to permit great flexibility and rapid forward thrust.

AMERICAN SNAKEBIRD (ANHINGA ANHINGA), SHOWING CHARACTERISTIC WING PATCHES OF THE MALE

SNAKE RIVER, one of the most important streams in the Pacific northwest section of the United States, is the largest tributary of the Columbia River. The drainage basin of the Snake (109,000 sq.mi. [282,000 sq.km.]) is 30% greater than the total area of Idaho and contains one-half the entire area of the Columbia River Basin in the United States. Runoff from Wyoming, Utah, Nevada, Idaho, Oregon, and Washington combines in this stream. From elevations of 10,000 ft. (3,048 m.) the river descends to an elevation of 300 ft. (91 m.) and contributes 36,820,000 ac-ft. (45,417,470,000 cu.m.) of water annually to the Columbia.

The river rises in high, rugged mountains of the continental divide near the southeast corner of Yellowstone National Park in Wyoming. It flows south along the eastern base of the Teton Mountains, and swings northwest near the mouth of Greys River and enters Idaho. Near Heise, the river leaves the mountains and crosses southern Idaho in a huge, southwesterly curving arc that terminates near the junction of the Boise and Snake rivers on the western edge of Idaho. Turning north, it forms the Oregon-Idaho boundary for 216 mi. (348 km.). From the northeast corner of Oregon it forms the Washington-Idaho boundary to Lewiston, Ida., and then turns west to join the Columbia near Pasco, Wash. Its total length is 1,038 mi. (1,670 km.).

The upper Snake River, above King Hill, Ida., is used to irrigate over 1,500,000 ac. (607,050 ha.) of land and to generate electric energy. The main stem is regulated by Jackson Lake, Palisades, American Falls, Minidoka, and Milner reservoirs. Principal tributaries below Heise are Henrys Fork (the largest), Blackfoot, Portneuf, Raft, Little Wood, and Big Wood rivers. The last two and Henrys Fork enter the river from the north. Other north side streams sink into Snake River plains and become part of an immense underground reservoir. Numerous large springs—outpourings of the underground water body—emerge from the canyon walls in Hagerman Valley. Twin Falls and Shoshone Falls, with drops of 65 and 212 ft. (20 and 65 m.), respectively, are located downstream from Milner Dam.

The central Snake River, from King Hill to Weiser, Ida., is used primarily for hydroelectric generation. Over 1,000,000 ac. (404,700 ha.) of land are irrigated in this section, primarily from tributary streams. Principal reservoirs and their associated rivers are Lucky Peak, Arrowrock, and Anderson Ranch on the Boise; Cascade, Deadwood, and Black Canyon on the Payette; Owyhee on the Owyhee; and Warm Springs and Agency on the Malheur.

The lower Snake River, from Weiser to the mouth, flows through a 1-mi. (2-km.)-deep gorge known as Hells Canyon, one of the deepest river gorges in North America. Salmon River, largest tributary and most important wildlife area of the river system, joins the main stem near the downstream end of the canyon section. (G. V. Sk.)

SNAKEROOT. In most countries where snakes abound some root or herb is used by the natives as an antidote for the bites of venomous species, and many herbs have consequently received the name of snakeroot. Botanically speaking, the name properly belongs to *Ophiorrhiza mungos*, a plant of the family Rubiaceae, used in Indonesia for the purpose above indicated. In medicine, however, the roots of *Aristolochia serpentaria*, *Polygala senega*, and *Cimicifuga racemosa* were understood by this name being distinguished as the Virginian, seneca, and black snakeroots. The root of *Aristolochia reticulata* is known in the United States as Red River or Texas snakeroot.

The roots, or rhizomes, of *Liatris spicata*, *Eryngium aquaticum*, and *Eupatorium rugosum* have all been used in North America for snake bites, the first two species being known as button snakeroot and the last as white snakeroot. The rhizome of *Asarum canadense* passes under the name of Canadian snakeroot. All of these contain acrid or aromatic principles that, when given in a warm decoction, exercise a powerfully diaphoretic or, in some cases, diuretic, action, to which the benefit, if any, derived from their use may be attributed.

SNAPDRAGON, any herbaceous plant of the genus *Antirrhinum*, of the snapdragon or figwort family (Scrophulariaceae), of which there are over 40 species, scattered over the North Temperate Zone, especially in the western states of the U.S. The common garden snapdragon, *A. majus*, much grown for its handsome flowers, is a perennial from the Mediterranean region, usually grown as a summer annual; growers for the florist trade, however, force it for winter bloom. It is a stout plant 12–25 in. high, producing pouchlike, irregular flowers in a showy terminal cluster (raceme).

A. W. KERR

A VARIETY OF SNAPDRAGON, ANTIRRHINUM MAJUS

Another species is the beautiful chaparral snapdragon, *A. coulterianum* of California, with purple or white flowers that have conspicuous yellow hairs in the throat of the corolla.

Scores of showy garden varieties have replaced the typical *A. majus*. They are dwarfs (6–9 in. high), intermediates (10–20 in. high), and talls (20–40 in. high).

For outdoor culture, seeds are shallowly sown in late summer and wintered in cold frames for transplanting the following spring. In all cold regions this must be done annually, for snapdragons are not frost-hardy. When forced for winter bloom seed is sown in early summer, and the potted seedlings are transferred to a cool greenhouse in late summer.

Snapdragon is also the somewhat inappropriate name of *Galvesia speciosa*, closely related to *Antirrhinum*, an evergreen shrub with showy scarlet flowers, found on the islands off the coast of California. (N. Tr.)

SNELL (van Roigen), **WILLEBRORD** (1591–1626), commonly known as Snellius, Dutch astronomer and mathematician the discoverer of the law of refraction, was born at Leiden. In 1613 he succeeded his father, Rudolph Snell (1546–1613), as professor of mathematics in the University of Leiden. In his *Eratosthenes Batavus* (1617), he describes his method of measuring the earth, and gives as the result of his operations between Alkmaar and Bergen op Zoom a degree of the meridian equal to 55,100 toises (=117,449 yd.). His discovery (1621) of the law of refraction was of significance for the study of the nature of light (*see* Light: *History*).

Snell died at Leiden, Oct. 30, 1626.

SNELLMAN, JOHAN VILHELM (1806–1881), Finnish philosopher, statesman, and rouser of Finnish nationalism during

the period when Finland was under Russian rule, was born at Stockholm, Swed., on May 12, 1806. He studied at the University of Turku and received his B.A. degree in 1831 at Helsinki, where he became instructor in philosophy in 1835. In 1841 Snellman published a philosophical work, *Die Idee der Persönlichkeit*, and in 1842 appeared *Läran om staten* ("Political Science"), in which, leaning on Hegel, he showed that the essence of a state is a national spirit.

The publication of the *Kalevala* (*q.v.*) in 1835 had initiated an interest in developing a national literature in Finnish. Regarding this as essential to the growth of a national spirit, Snellman began his revolutionary influence as a stimulator of the national cultural life in 1844, when he started publication of the *Farmer's Friend* (*Maamiehen ystävä*) and the Swedish-language paper *Saima* (suppressed in 1846). Later, with Elias Lönnrot (*q.v.*), he edited at two different periods the paper *Litteraturblad för allmän medborgerlig bildning* ("Literary News for General Civic Culture"). In 1856 Snellman was named professor of "ethics and the system of sciences" at Helsinki, and from 1863 to 1868 he was a senator. He exerted a decisive influence on the promulgation of the 1863 statute extending the use of the Finnish language. He was also active in promoting the 1865 legislation that changed the basis of the monetary standard from rubles to marks. Snellman was knighted in 1866. He died July 4, 1881, at Kirkkonummi.

Snellman's *Collected Works* (*Kootut teokset*) were published in Finnish in 1928–33, the *Correspondence* (*Kirjeenvaihto*) with his wife in 1928. *See* also FINLAND: *History: Autonomy Under Russian Rule*; FINNISH LITERATURE. (F. P. M.)

SNIPE, a shore bird of the sandpiper family (Scolopacidae), much sought after as game. The common snipe (*Capella gallinago*) of Europe and America is 11 in. long with a long ($2\frac{1}{2}$–3 in.) bill, eye placed far back in the head, rather short legs, but long toes, a very short tail, and a complicated pattern of brown, buffs, and black on its upper parts. It lives in bogs and wet meadows where it probes for worms.

Secretive, it flushes from the grass with a hoarse cry and zigzags rapidly away. The birds, though usually solitary, sometimes feed and travel in loose flocks. They winter south to Africa, Java, and South America. In the spring the male gives a flight song, the pair lines a hollow in the ground for a nest; four spotted eggs are laid and incubated by the female; and the active, downy young are cared for by both parents.

There are other related species in Europe, Asia (some of which migrate to Australia), Africa, and South America. A more different species, the jacksnipe (*Lymnocryptes minimus*) of Europe, is only $7\frac{1}{2}$ inches long. In Europe, dowitchers are also called snipe.

The species of painted snipes, one of Africa and the area of southern Asia and Australia, the other of South America, form a related family, Rostratulidae, in which the birds are more brightly coloured; in this family the female is larger and brighter than the male, and takes the initiative in courtship, while the male incubates the eggs. (A. L. RD.)

SNOILSKY, CARL JOHAN GUSTAF, COUNT (1841–1903), Swedish poet, the most notable of a group of early poetic realists, was born in Stockholm on Sept. 8, 1841. At Uppsala University Snoilsky made himself known by his great poetic talent. He went to Italy in 1864 and wrote poems praising the joy and beauty of the Mediterranean landscape. After several years as a diplomatist and civil servant he gave up his career in 1879 and lived abroad, devoting himself to poetry. Deeply affected by social problems, he favoured the breaking down of class barriers and expressed his social anguish and humane liberalism in important poems. From these years also dates his well-known series on figures and episodes from Swedish history, *Svenska bilder* (1886). In 1890 Snoilsky returned to Stockholm, where he died on May 19, 1903. Snoilsky's poetry is clear and elegant and has, though rather traditional in form, a strong note of realism.

SNORRI STURLUSON (1179–1241), Icelandic historian and author of the *Prose Edda* (*see* EDDA). A descendant of the great poet Egill Skallagrímsson, he was born in 1179 in the west fjords, but from the age of three was brought up at Oddi in the south, at the home of Jón Loptsson, the most influential chieftain in Iceland. Jón was a grandson of Saemund Sigfússon (Saemundr the Wise), the first known Icelandic historical writer, and of Magnus II Barfot (Bareleg), of Norway. Like many chieftains, Jón was an ordained priest, and he was keenly interested in historical traditions. From him Snorri acquired both a deep knowledge of Icelandic tradition and a European breadth of outlook.

Jón died in 1197, and in 1199 Snorri married an heiress in Borgarfiord (Borgarfjordhur), and began to acquire lands and power. In 1206 he settled at Reykjarhóll, where most of his works were written. There he built a magnificent house, with a tiled bath, heated by volcanic springs. During 1215–18 (and again during 1222–32) he was *lǫgsǫgumaðr* ("lawspeaker" or president) of the Icelandic high court. In 1218 he was invited to the Norwegian court by King Haakon IV; he also visited noble families in Sweden, acquiring an unusual knowledge of Swedish tradition.

While in Norway, he began to intervene in politics. A quarrel had broken out between the Bergen merchants and Icelanders from Oddi, and the Norwegians were planning a punitive raid. Snorri persuaded Haakon that he could become king of Iceland by peaceful means, and promised to win the Icelanders over to him. He became Haakon's vassal (*lendrmaðr*), and on return to Iceland in 1220, sent Haakon his son as hostage. However, he did little to further Haakon's cause; and, in revenge, Haakon stirred up a feud between him and his kinsman, Sturla. Snorri was outlawed and fled to Norway (1237), there joining the faction of Earl Skúli. In 1239, hearing that Sturla had fallen in battle against Gissur Thorvaldsson (Snorri's son-in-law), Snorri returned to Iceland against Haakon's express command. In 1240 Haakon defeated Earl Skúli, and ordered Gissur to kill Snorri, or send him captive to Norway. Gissur attacked Snorri in Reykjarhóll, and killed him on Sept. 22, 1241.

Snorri's writings are remarkable both for their scope and for their formal assurance. In the *Prose Edda*, he succeeds in arranging the legends and drawing meaning from them, and in communicating his enjoyment of them as stories. He also explains the ornate diction of the ancient scaldic poets, telling the heroic legends to which their metaphors allude, and illustrates the great variety of poetic metres, often with his own verses.

Though he also composed court poems in honour of great men, his greatest gift was in prose. As well as the *Prose Edda*, he wrote a life of St. Oláf of Norway, included in the *Heimskringla*, a history of the Norwegian kings from their mythological origins as descendants of Oðinn down to Magnus Erlingsson (1184). For this, he used earlier histories, but he had gathered much fresh material. He particularly valued poems handed down orally from the time of the events themselves, and selected the traditions that seemed to him most authoritative and true both to contemporary politics and to human nature. To him, the writing of history meant the reconstruction of action, motives, and dialogue: his genius lay in his power to present with the immediacy of drama all that he perceived critically as a historian.

To Snorri is also attributed, almost certainly correctly, *Egils Saga*, one of the greatest of the Icelandic sagas.

The qualities of intelligence, warmth, and scholarly industry in Snorri's writing contrast sharply with the weak, shifty character that emerges from the account of his life by his nephew preserved in the *Sturlunga Saga*. Cold and miserly toward his family, opportunist in politics, he was ambitious for greatness but lacked the courage and willpower necessary to achieve it.

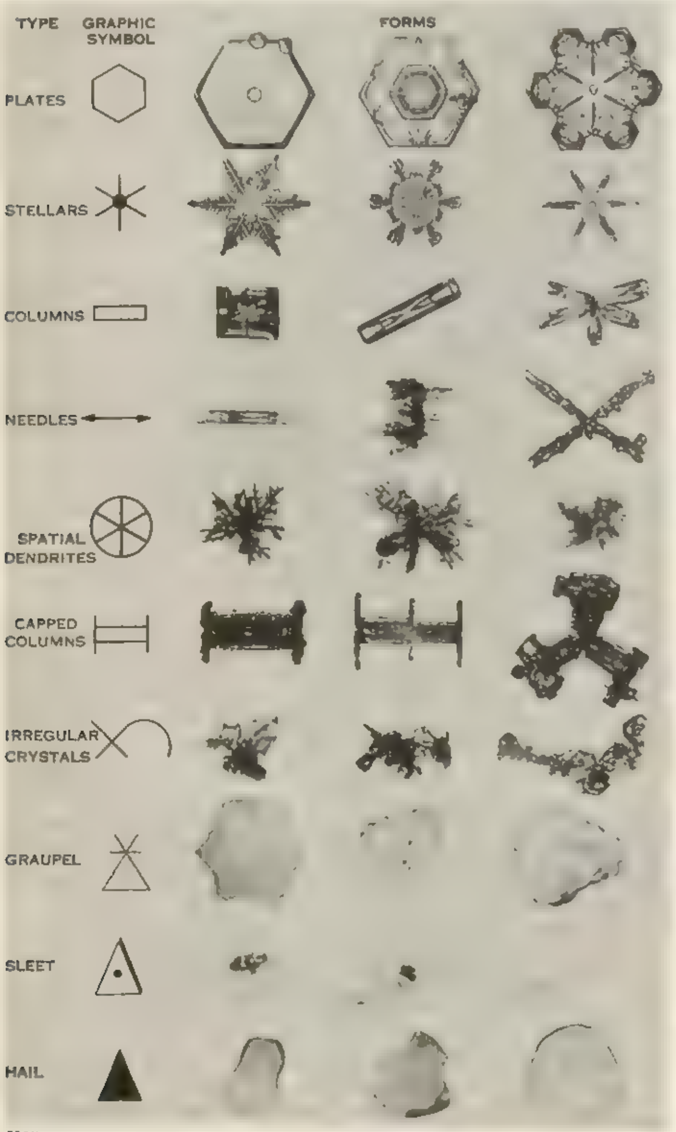
SNOW is the solid form of water which grows while floating, rising or falling in the free air of the atmosphere. It often takes the form of beautiful crystals generally having a hexagonal pattern. Snow crystals sometimes come from a cloudless sky since they may form spontaneously or in the presence of suitable sub-

limation nuclei before there is enough water vapour present in the air to form the common water droplet cloud.

Snow has attracted the attention and admiration of man from ancient times. The word crystal is of Greek origin and is derived from *kryllos*, the word for frost. One of the first indications of man's early awareness that there was more to snow than cold, hunger, trouble, and restricted travel is the biblical reference to the "storehouses of the snow" in the Book of Job 38:22.

One of the first recorded instances showing recognition of the hexagonal symmetry of snow crystals is ascribed to Olaus Magnus, archbishop of Uppsala in Sweden, who depicted the crystal form in a book on natural phenomena published in Rome in 1555. The development of the microscope increased this knowledge. Robert Hooke of England studied the snow crystal structure and published illustrations of some of the beauty and symmetry he saw in his fascinating book, *Micrographia*, published in 1665. During the middle of the 19th century, poetry and prose were written about snow and snow crystals. An extremely interesting book of this period entitled *Cloud Crystals* written by "A Lady" and published in 1864 contains scientific fact, poetic fancy and excellent wood cuts showing some of the basic forms of snow.

Snow Crystals.—It has been said that no two snow crystals are the same. This statement is true in the sense that it is quite unlikely that among all the countless myriads that fall from the sky there are ever two identical in shape, size and absolute number and distribution of water molecules.



FROM "ARTIFICIAL STIMULATION OF RAIN" (1957); REPRODUCED BY PERMISSION OF PERGAMON PRESS, INC.

CLASSIFICATION OF FROZEN PRECIPITATION

However, it is no problem during a particular storm to observe two crystals which to the unaided eye or even at low-power magnification are similar in outline and general structure. The main point to observe in this relation is that there is a bewildering variety of size, shape and pattern. They range from simple, solid triangles and hexagons to the exquisite fernlike dendrites, with all manner of complicated three-dimensional formations.

In an attempt to simplify the task of the research scientist concerned with reaching a better understanding of the fundamental science related to the formation of snow and ice, a classification of solid precipitation was developed in 1951 for international usage. This is shown in the accompanying figure which illustrates the typical forms of ten types of frozen precipitation. It is quite feasible to subdivide any one of these ten types into subtypes and for special purposes this is being done. For all practical purposes, however, the types illustrated can be used to describe the precipitation of snow, ice and hail storms.

A considerable amount of the popular interest in snow crystals stems from the pioneer and classic photographic work done by Wilson W. Bentley, farmer-meteorologist of Jericho, Vt. Bentley became enthralled by the beauty of snow crystals and spent many winters with his camera, recording the varieties and symmetry of the crystals that are such a common feature in the vicinity of his northern Vermont home. Of the more than 5,000 photomicrographs prepared by him, nearly half have been perpetuated in *Snow Crystals*, published in 1931. His persistent efforts, careful observations and beautiful photographs did much to arouse the interest of scientists in snow crystals

In Europe a similar effort was expended by A. B. Dobrowolska of Poland who wrote many scientific articles on this subject. In Japan, the classic work in the study of snow by U. Nakaya of the University of Hokkaido culminated in his book *Snow Crystals* (1954).

The relationship of snow to ice and the peculiar underwater snow storms caused by frazil (needle, or lolly) ice formations have been studied for many years and are of much economic importance.

The bewildering variations and modifications occurring in snow after it has reached the ground are a specialized study that still continues. The early studies have been well summarized by G. Seligman. The modern work increases in complexity with much of it in North America under the leadership of the Snow, Ice and Permafrost establishment of the U.S. army corps of engineers.

There are many factors controlling the size and shape of snow crystals. One of these—probably the most important—is the supply of water molecules in the air. If the air contains a rich supply of moisture, the snow crystals will grow fast and are likely to have dendritic or fernlike arms, will be large and may clump together with others to form a snowflake. Snowflakes may have 50 or more crystals interlocked with each other. If a stellar-type crystal forms or falls into a cloud containing a high density of subcooled cloud droplets, it may sweep up some of them which freeze upon contact and cover the crystal until it looks like a miniature snowball. Such particles are called soft hail or snow pellets but are most commonly called by the German name *graupel*.

The temperature of the air is another condition controlling the form of the snow crystal. If the air is colder than about −30° C. it contains very little water vapour so that any crystals developing grow very slowly and are likely to be tiny, dense and compact in shape and crystal form. This is the condition which produces the crystals of the filmy cirrus clouds that form in the high levels of the atmosphere often at altitudes of five to eight miles over the middle and low latitudes. In the polar regions, cirruslike clouds may be close to the ground due to the intense cold.

At temperatures close to −40° C. (−40° F.) which commonly occur in the polar regions and at levels in the sky above 30,000 ft., ice crystals form spontaneously whenever a sufficient concentration of water molecules exceeds the amount that can exist in vapour form. This is called homogeneous nucleation phenomenon. At all temperatures warmer than −40° and colder than 0° C. (32° F.), heterogeneous nucleation occurs. In this range special type microscopic or submicroscopic particles floating in the air serve as nuclei for ice crystal formation. Particles in the

size range of 0.01 to 10 μ (0.00000039 to 0.00039 in.) in diameter, consisting of such materials as volcanic dust, loess, certain types of clays, silver iodide and a special form of copper sulfide, serve as effective ice nuclei. Except for the silver iodide and copper sulfide, which become active at temperatures colder than −4° C., most ice nucleating substances are effective in the temperature range of −12° to −25° C. There is much still to be learned about the behaviour and characteristics of such particles.

Effects of Snow.—Like so many of the small things in nature, a snow crystal, when considered as a single particle, is at once beautiful or at least interesting in structural form and seemingly ineffectual as an element of force or destruction. It is only when they occur in quantity—nearly countless numbers—that their presence causes wonder, interest, concern or terror.

Floating in the rare air of the high atmosphere, the tiny, pointed or flat-ended hexagonal columns and thickened hexagonal plates form the coloured halos, pillars, arcs and circles surrounding the sun in orderly array. Formed in the upper parts of turbulent clouds, the reactions between crystals and subcooled water cause the development of electrical charges often manifested as cloud-to-cloud or cloud-to-ground lightning and radio static and lesser degrees of atmospheric electricity. Sweeping over and smashing on airplane wings and fuselage, the snow crystal causes electrification which may appear as St. Elmo's fire (*q.v.*) on leading surfaces and may illuminate the trailing edges of the wing tips.

Much of the moderate to heavy rain in the middle latitudes starts as snow in the high reaches of the sky and thus is responsible for the precipitation on which most life as we know it is primarily dependent. Snow packs (the annual accumulations of snow at higher elevations) represent a form of water storage that is very useful to man. The heavy winter snows in the higher elevations remain as a slowly melting snow pack long into the summer, feeding the mountain streams flowing into the drier valleys. The interior valleys of California and Oregon, plains of Utah, Colorado, New Mexico, Arizona, parts of Spain, north Africa and a number of similar areas which have insufficient precipitation to support crops are made into fertile agricultural regions by means of irrigation water from nearby massive mountains.

At times snow may become so deep and unstable on the mountain slope as to form a terrifying avalanche or it may become consolidated to form massive layers of turquoise green-blue glacial ice to flow down the mountain as a river of ice (*see* AVALANCHE; GLACIER).

It would not be proper to end the discussion of the massive effects of snow without reference to the beauty of snow and the sport of skiing. With the rapid development in the second half of the 20th century of ski centres and ski lifts of all kinds, and the equipment demanded by the skier, the importance of snow as a valuable commodity in certain areas assumed such value that it became economically profitable to generate snow on cold nights from high-pressure air and cold water.

For an account of the history of this sport and a description of its development throughout the world *see* SKIING. *See* also SNOWSHOE.

Snow Crystals and Cloud Modification.—When the droplets in clouds cool below 0° C. (32° F.), they do not normally freeze but remain in liquid form. These subcooled droplets may cool to −30° C. or colder before they freeze, depending on whether or not they contain freezing nuclei or float near ice crystals. Whenever water subcools, it becomes unstable, so that an ice crystal alongside a liquid droplet will grow at the expense of the droplet. If nuclei suitable for ice crystal nucleation enter a cloud, they grow rapidly and either transform the entire cloud to snow or grow until large enough to overcome rising currents in the air and thus fall out of the cloud.

Since, as shown by V. J. Schaefer in 1946, it is feasible to produce local concentrations of ice nuclei in greater numbers than occur under natural conditions and having a nucleating activity better than naturally occurring particles, scientists are able to carry out experiments using clouds in the atmosphere for their subjects. Efforts are being made to take advantage of these opportunities, to prevent damaging hailstorms, to modify lightning storms, to increase snow deposits in the high mountains, to increase rainfall and to moderate or prevent the development of disastrous storms.

These local efforts may eventually lead the way to large-scale weather control. Although some evidence has been found that other methods may be useful to modify clouds, the ice nucleus and the snow particle which grows on it seem likely to remain of great importance in the science of experimental atmospheric physics.

Snow Crystal Replicas.—The form and appearance of the fragile and evanescent snow crystal may be preserved in minute detail by an extremely simple and effective process of replication. A dilute 0.5 to 3% solution of polyvinyl formal (a plastic) dissolved in ethylene dichloride (a common solvent) is required to make the replica. The solution must be cooled a few degrees below 0° C. (32° F.) before using. A small amount of the replica solution is poured onto a piece of black cardboard, sheet glass or similar material that also has been cooled below 0° C. The wet surface is then placed so that snow falls into it. When the desired number of crystals have fallen into the solution, it is placed in a cold, well-ventilated place until the solvent evaporates. This ordinarily requires 5 to 10 minutes. When the sample is dry, it may be warmed up and examined. When properly prepared, each crystal is encased in a thin plastic shell whose inner surface is an exact negative copy of the original crystal. When the crystal melts, the water passes through this thin film, leaving behind a hollow cavity which reflects and scatters light in a manner quite similar to that of the original crystal. Frost, fallen snow and related substances may be replicated in a similar manner.

SNOWDEN, PHILIP SNOWDEN, VISCOUNT (1864–1937), British statesman, outstanding socialist propagandist and first Labour chancellor of the exchequer, was born at Ickornshaw, Cowling, Yorkshire, on July 18, 1864, the son of a weaver. He was educated at an elementary school. For a few years he was a clerk in the customs and excise department of the Inland Revenue, but in 1891 a spinal disease, which left him permanently crippled, forced him to abandon this work. When partial recovery came he devoted himself to full-time political activity for the Independent Labour Party (I.L.P.). He was perhaps the most effective of all those devoted and peripatetic political evangelists who symbolized the early activity of the I.L.P. For many years the whole of his meagre income came from lecturing and writing for socialist papers.

Unsuccessful in the 1900 general election at Blackburn, Yorkshire, he represented that constituency from 1906 to 1918, and Colne Valley, Yorkshire, from 1922 to 1931. Snowden was a formidable parliamentarian, whose character and command of fact and argument more than offset the bitterness of his manner. He initiated some of the most memorable pre-1914 debates on social and economic questions. When World War I broke out he unhesitatingly took the pacifist side, and shared with J. Ramsay MacDonald much of the resultant unpopularity. He was far from being an extremist, however. Before 1914 he had criticized the strike policy of the more militant trades unionists, and in 1921 he resigned the treasurership of the I.L.P. in protest against what he regarded as the increasing intransigence of that body.

In 1924 Snowden became chancellor of the exchequer of the first

Labour government. His first budget broke little new ground but made some well-received reductions in indirect taxation. In 1929, in the second Labour administration, he was reappointed to the treasury, and immediately scored a popular success by insisting upon British rights at the Hague conference on German reparations (1929). Deepening unemployment meant that in 1930 he faced a far more difficult budgetary situation than in 1924, but he reacted by showing himself a rigidly orthodox financier, more attached to the maintenance of free trade than to anything else. He was responsible for establishing the famous May Economy Committee of 1931, the recommendations of which, particularly those relating to the reduction of unemployment benefit, led to the breakup of the Labour government on Aug. 24, 1931.

He continued as chancellor when MacDonald formed the National government, carrying through an emergency budget, with heavy cuts in expenditure, and presiding over Britain's departure from the gold standard at the end of September 1931. He did not stand at the election in October and in November he was created Viscount Snowden of Ickornshaw and became lord privy seal. However, he resigned in September 1932, in protest against the protectionist policy adopted at the Ottawa conference. He died at Elm Lodge, Tilford, in Surrey, on May 15, 1937. Snowden was never accused of careerism; he was rigid and arrogant, but high-principled and austere. His principal books were: *The Socialist's Budget* (1907), *The Living Wage* (1912), *Socialism and Syndicalism* (1913), *Wages and Prices* (1920), *Labour and National Finance* (1920), *Labour and the New World* (1921, revised edition, 1924), and *An Autobiography*, two volumes (1934). (R. J.)

SNOWDON (Y Wyddfa, "the viewplace"), the highest peak (3,560 ft. [1,085 m.]) in England and Wales, situated in Caernarvonshire, Wales. It is the main peak in the Snowdonian mountain mass (Welsh: *Eryri*, eagle place) which, bounded by the Arfon lowlands on the northwest and the vales of Ffestiniog and Conway on the south and east, includes the peaks Glyder-fawr (3,279 ft. [999 m.]), Glyder-fach (3,262 ft. [994 m.]), Carnedd Llewelyn (3,485 ft.), and Carnedd Dafydd (3,427 ft.). The vegetation of the area is mainly rough grassland; alpine flora survives only on some high rock ledges shaded from the sun. Below 800 ft. (250 m.; the present-day limit for tree growth) are patches of deciduous forest. Snowdon is formed principally of Ordovician volcanic rocks, slates, and grits. It consists of five arêtes (sharp ridges) converging on the summit, between which lie cirques (*see* Cirque). Surrounding the peak are the Llanberis, Aberglaslyn, and Rhyd-ddu passes. A rack-and-pinion railway (opened 1896) ascends from Llanberis to the summit (4½ mi. [7.6 km.]). Several lakes occur in the glaciated valleys which radiate out from Snowdon: Lakes Padarn and Peris separated by an alluvial fan in the valley below Llanberis Pass; Lakes Gwynant and Dinas in the Nant Gwynant valley.

Snowdonia National Park covers 845 sq.mi. (2,189 sq.km.) of the mountainous tracts of Caernarvonshire, Denbighshire, and Merioneth. Noted for the beauty of its mountain, valley, and lake scenery, it includes the Snowdonian mountain mass in the north, the Cader Idris (*q.v.*) in the south, and the National Forest Park (formed in 1937) west of the Conway valley. The Forestry Commission has been responsible for extensive planting in the Gwydyr and Beddgelert forests. Conifers predominate including Sitka spruce, European larch, and Douglas fir.

SNOWDROP, any plant of *Galanthus*, a small old world genus of the amaryllis family (Amaryllidaceae). All the plants of the genus have bulbs, linear basal leaves and erect flower stalks about one foot tall, bearing at the top a solitary, pendulous, bell-shaped white flower. Most especially, the term snowdrop indicates *G. nivalis*, the common snowdrop widely cultivated in the U.S. and England, often in naturalized masses in the lawn. Other distinct species are the Crimean snowdrop, *G. plicatus*, with broad leaves folded like a fan, and *G. elwesi*, the giant snowdrop, a native of the eastern Mediterranean with large (1¼ in. long) flowers.

SNOWDROP (GALANTHUS NIVALIS), ONE OF THE EARLIEST SPRING FLOWERS

All species thrive in almost any soil or position. The bulbs should be planted in autumn, 3 in. deep and about 3 in. apart, preferably by the hundreds if sheets of early white bloom—often before the winter snow disappears—are desired. (N. Tr.)

SNOW LINE, a line above which snow accumulates, temporarily (seasonal snow line) or perennially. Two types of perennial snow lines are recognized, orographic and regional. The orographic snow line passes through the lowest limit of perennial snow masses lying in protected spots. The regional snow line marks the lowest limit of an essentially continuous snow mantle, and its altitude depends primarily upon temperature and precipitation.

The regional snow line rises from near sea level in polar regions to 20,000–21,000 ft. (6,100–6,400 m.) in the horse latitudes and descends to 15,000–18,000 ft. (4,600–5,500 m.) in equatorial regions. The orographic snow line may be 2,000–3,000 ft. (600–900 m.) lower. *See* Climate and Climatology; Glacier. (R. P. Sp.)

SNOWPLOW, a device for clearing snow from streets, highways, railroad tracks, airfields, and the like. There are three general types of snowplows, known as rotary, V, and single-blade.

The rotary plow in railroad use is mounted on a carriage that is pushed by one or more locomotives. It consists of several large blades attached to a horizontal shaft powered by an engine mounted on the carriage. A housing is provided for the protection of the engine, the rotary controls, and the operators. The plow is forced into deep drifts or slides while the blades are rotating. The snow is sliced from the face of the drift and discharged to one side of the track. The rotary snowplow is generally used to remove snow in depths which cannot be handled with the V-plow.

Under some conditions flangers are used to remove snow from the inside of the top of the rail to avoid the formation of ice that might cause derailments.

The rotary plow for highway use is similar in design to that used for clearing railway tracks but is built into a self-propelled truck unit. In some cases pusher trucks may be used for additional power. An adaptation of the rotary plow is a unit consisting of two or more augers which feed the snow from the left and from the right to a centre collecting point from which a high-speed rotor discharges the snow to one side of the right-of-way. This unit is frequently mounted on the front of a standard motor grader or special heavy truck.

The V-plow consists of two concave surfaces fastened to a common centre line and sloping upward and to the rear, one to the right and one to the left. The V-plow forces the snow to either side and is used in areas of heavy snow, deep drifts or slides. For clearing railroad tracks the V-plow is mounted on a carriage pushed by one or more locomotives. In some mountainous areas the plows are mounted directly on the front of steam locomotives. The V-plow for highway clearance may be mounted on a heavy-duty truck, motor grader, or tractor.

The single-blade plow may consist of a concave surface of varying depth or a straight blade. The former moves the snow in one direction only; the straight-blade type is reversible and may be set to move the snow to the right or left. The single-blade plow mounted on a heavy-duty truck is commonly used on highways and airports. The trucks operate at relatively high speed to throw the snow well off the travel way. A wing may be attached back of and above the single-blade plow. It may be adjusted to direct snow away from the plowed way. (F. W. St.)

SNOWSHOE, a form of footgear devised by Eskimos and some Indians for traveling over deep snow. Whereas skis were

adopted in the Old World, snowshoes had more practical applications in the forested areas of North America where evidence suggests that the frame snowshoe was independently invented in several regions.

The most important parts of a snowshoe are the wooden frame, usually of birch or hickory, a toe and heel crossbar of wood or rawhide, extra strengthening bars, netting in large meshes, and foot lashing for attaching the shoe or moccasin. The size of the mesh varies, a coarser mesh being used for wet, soft snow.

Snowshoes differ in materials, size, shape, and decoration, depending on the people who make them and the conditions under which they are used. The variation in shapes is particularly great. The frames, usually 2 to 5 ft. (0.6 to 2 m.) long and 1½ ft. (0.5 m.) wide, help to distribute the body weight over a wide area to keep the wearer atop the snow. Indians like the Montagnais and Naskapi of the Labrador Peninsula, who subsist by trapping and hunting large game animals in an environment having as much as 60 to 120 in. (150 to 300 cm.) of snowfall annually, need snowshoes for a variety of kinds of winter travel. Thus their five distinct types, descriptively named from the shapes of the frames, are bear-paw, swallow tail, beaver tail, elbow, and pointed.

Walking in snowshoes is accomplished by lifting the feet slightly and sliding the overlapping inner edges of the shoes over each other, avoiding the unnatural "straddle gait" that would otherwise be necessary. Snowshoe racing, common in the U.S. and Canada, is a popular event at winter carnivals. (J. W. VanS.)

SNUFF, a powdered preparation of tobacco (*q.v.*) used by inhalation or by "dipping"; *i.e.*, rubbing on the teeth and gums. The practice of inhaling snuff became common in England around the 17th century, and throughout the 18th century it was universal.

At first each quantity was fresh grated (Fr. *râper*, whence coarser kinds were later known as "rappee"). This entailed the snuff taker's carrying with him a grater; early 18th-century graters made of ivory and other material are in existence. The art and craft of the miniature painter, the enameler, jeweler, and gold- and silversmith were bestowed upon the box. Humbler snuff takers were content with boxes of silver, brass or other metal, horn, tortoiseshell, or wood.

The mull, a silver-mounted ram's head, is a large table snuffbox.

Snuff manufacture, which requires 18 to 20 months, involves grinding the tobacco and subjecting it to repeated fermentations. Snuffs are scented with attar of roses, lavender, cloves, jasmine, etc.

SNYDERS, FRANS (1579–1657), Flemish painter of animals and still life, was born at Antwerp, where he was baptized on Nov. 11, 1579. He studied under Pieter Brueghel the Younger, and afterward under Hendrick van Balen, the first master of Van Dyck. He visited Italy in 1608. On Oct. 23, 1611, he married Margaretha de Vos, the sister of the painters Cornelis and Paul de Vos. He died on Aug. 19, 1657.

Snyders originally devoted himself to painting flowers, fruit, and subjects of still life, later turning to animal painting and executing with the greatest skill and spirit hunting pieces and combats of wild animals. His composition is rich and varied, his drawing correct and vigorous, his touch bold and thoroughly expressive of the different textures of furs and skins. Rubens frequently employed him to paint animals, fruit, and still life in his own pictures, and he assisted Jordaens similarly. In the lion and boar hunts that bear the name of Snyders the hand of Rubens sometimes appears. Snyders was appointed principal painter to the archduke Albert, governor of the Low Countries, for whom he executed some of his finest works. One of these, a "Stag Hunt," was presented to Philip III, who commissioned the artist to paint several subjects of the chase. The Prado Museum, Madrid, is rich in the works of Snyders. Others may be seen at the Museum of Fine Arts, Boston, Mass. ("Boar Hunt"); the California Palace of the Legion of Honor, San Francisco ("The Monkey and the Gander"); the Kaiser Friedrich Museum, Berlin ("Bear Hunt"); and at many other public galleries.

SOANE, SIR JOHN (1753–1837), English architect, one of the most original architects of his time in Europe, was born at Goring-on-Thames, Sept. 10, 1753, son of a bricklayer. In 1768 he entered the office of George Dance the Younger, surveyor to the City of London, whom in later life he referred to as his "revered master"; in 1772 he went to Henry Holland (*q.v.*) as an assistant; and from 1771 he attended the Royal Academy schools, winning the gold medal in 1776. In 1778 the king's traveling studentship took him to Italy. He cut short his studies abroad because of magnificent promises of employment made to him by Frederick Hervey, bishop of Derry. These were not kept, and he was an only moderately successful country house architect until in 1788 he was appointed, thanks to William Pitt, surveyor to the Bank of England. Various government appointments followed and in 1806 he succeeded Dance as professor of architecture at the Royal Academy; he was knighted in 1831. The list of his works is a long one; some of the finest, which helped establish his reputation, included his rebuilding of the Bank of England (since rebuilt again), his own house at 13 Lincoln's Inn Fields, London (left by him to the nation as a museum), and the Dulwich College art gallery, Kent. His style is characterized by a tendency to strip classical elements of design down to their structural essentials, the substitution of linear for modeled ornamentation, frequent use of shallow domes and top lighting, and an ingenious and often highly imaginative handling of interior space. Soane died on Jan. 20, 1837, in London.

SOAP may be defined as either a chemical compound or a mixture of chemical compounds resulting from the interaction of fatty oils and fats with alkali; *i.e.*, the salts of fatty acids. Functionally, soap is a substance possessing the characteristic "soaplike" properties of sudsing, detergency, surface tension lowering, wetting and emulsifying power, and curd and gel formation. Modern research has led to the view that these properties may be attained by inserting strongly polar (water-soluble) groups into a wide variety of long-chain molecules. Many such long-chain substances, some of them bearing no relation to the fats, have been developed, and some of them (*e.g.*, sulfated alcohols, sulfonates, etc.) are of commercial importance in the field of soaps. The functional consideration of soap brings within its scope these synthetic detergents and at the same time excludes the water-insoluble compounds of fatty acids with bases of calcium, iron, aluminum, etc. These latter are better termed "metallic soaps."

Soap appears first to have been made by boiling goat tallow and causticized wood ashes, as described by Pliny. The resulting soft potash soap was converted into hard soda soap by treating the paste repeatedly with salt. In the 13th century the industry was introduced from Italy and Germany into France, and in the 14th century into England. In America soapmaking was a household art, with few industrial developments until after about 1800.

The processes and extent of soap manufacture were revolutionized during the first half of the 19th century as a result of M. E. Chevreul's classical researches on the constitution of oils and fats and of the introduction of the Leblanc process (invented in 1791) for the manufacture of soda from brine. Large-scale manufacturing operations developed, and the industry rapidly became able to process individual kettles of soap containing from 100,000 to 1,000,000 lb. per charge.

Chemistry of Soap.—All fatty oils and fats are mixtures of glycerides; *i.e.*, compounds (esters) of the trihydric alcohol glycerol (glycerin) and some fatty acid such as palmitic acid, etc. The chemistry involved in soap manufacture may be expressed in the following equation:

$$\underset{\substack{\text{palmitin}\\ \text{(fat)}}}{C_3H_5(OCOC_{15}H_{31})_3} + \underset{\text{caustic soda}}{3NaOH} = \underset{\substack{\text{soap}\\ \text{(sodium palmitate)}}}{3NaOCOC_{15}H_{31}} + \underset{\text{glycerol}}{C_3H_5(OH)_3}$$

The reaction of the fat with the aqueous caustic solution is termed saponification. (The term may also refer to the action of water on a fat to produce fatty acid.) As seen in the equation, the saponification reaction produces both soap and glycerol. The

usual method of manufacturing soap requires a further series of operations to separate the glycerol from the soap and bring the soap to the correct physical form (or phase).

Commercial soap products are essentially soap-water systems, the properties, form, and appearance of the product depending in great degree on the proportion of soap to water. Strictly anhydrous (water-free) soap has none of the usual soaplike properties and therefore is not used.

At room temperature for most of the potash soaps and at more elevated temperatures for the soda soaps, soap-water systems exhibit a variety of physical forms, or phases. These different phases, described below, are the materials with which the soap maker works and from which his products are derived. For example, true soap solutions (called nigre phase) occur when the proportion of soap to water is under about 30% (varying from soap to soap). In potash soaps the solutions, with some modification with glycerol or alcohol, form the liquid soaps of commerce. (Special compositions of soap solutions containing electrolytes constitute the nigres of the soap kettle.) When the soap-water system contains about 40–50% water, a different phase of soap results. This phase is called middle soap, or gum soap; when derived from potash it is sometimes sold as a soft soap. Middle soap is stiff and viscous, much more so than either more dilute or more concentrated systems. At concentrations approximating 70% soap–30% water, a form called neat soap occurs. Neat soap when cooled and solidified is converted into "framed," or unmilled, bar soap. It is the starting material for the vast majority of toilet, laundry, and household soaps, since it is produced as the final product of the soap kettle or hydrolyzer; it is then further processed as occasion requires (*see* below). When neat soap is diluted with water, instead of becoming less viscous, as is the usual rule, it becomes more viscous due to formation of middle soap.

At concentrations of about 85% soap, solid (crystalline) forms of soap become increasingly predominant. Most powders, beads, and flakes are made in this low moisture range (usually below 10%) and hence are substantially crystalline in nature.

Since the great bulk of commercial soap products is derived from saponification with a soda base, it is sufficient to consider further the soda soaps alone. Dilute solutions of the order of 0.1–0.5% are used for laundering and dishwashing. Such solutions (nigre phase) are relatively thin and fluid, but more concentrated hot solutions when cooled are either opaque jellies or semisolid masses. The frothing or sudsing of soaps occurs only in the solution (nigre) state. Neat, middle, waxy, and solid forms do not foam or suds until water is added to transform them, at least partially, to nigre. Thus, while soaps are ordinarily manufactured and sold in one of the concentrated phases, their usefulness in cleansing comes about after their conversion to the nigre, or solution, state by means of water.

Neat and middle soap are anisotropic, liquid crystalline phases. Nigre is an isotropic, colloidal solution. The solid, crystalline forms of soap are called alpha, beta, delta, and omega, each of the last three contributing its distinctive properties when present in bars, powders, and pastes.

The peculiar colloidal and electrical properties of the solution, or nigre, form of soap have led to the classification of soap as a colloidal electrolyte. At very low concentrations (of the order of 0.001%) the dissolved soap is hydrolyzed to a degree by the water to form free fatty acid and small amounts of free alkali. At slightly higher concentrations, acid soap (*e.g.*, sodium hydrogen palmitate) precipitates, causing much of the cloudiness seen in dilute soap solutions and liquid soaps. The molecules of dissolved soap and soap ions in solutions of the order of 0.1% concentration begin to clump together to form "neutral colloid" and colloidal "ionic micelle," which may be hydrated. The colloidal ionic micelle (which may be thought of as an electrically charged colloidal particle) and other ions give the solution pronounced electrical conductivity in contradistinction to ordinary colloids.

The behaviour of a pure, single, anhydrous soap when heated is very complex and has led to much confusion about the melting points of soaps. The solid soap when heated is converted in turn at definite transition temperatures to subwaxy soap, waxy soap, superwaxy soap, subneat soap, neat soap, and finally to nigre.

Only the compounds prepared from fatty acids of between about 10 and 18 carbon atoms in chain length can be considered soaplike under usual conditions. Indeed, sodium stearate (18 carbon atoms) possesses practically no soaplike properties at room temperature; it is only at temperatures approaching the boiling point of water that this compound behaves like a soap.

Detergent Power.—The washing or detergent power of soap was formerly attributed to the alkalinity produced by hydrolysis of the soap. Though this explanation has been abandoned, no comprehensive substitute explanation based on adequate experimental data has yet been established in its place. The detergent action of soap is an intricate phenomenon in which wetting power, emulsification, ability to dissolve grease, etc., all play a role. A widely held and plausible hypothesis has considered that washing is dependent on an unsymmetrical structure inherent in the soap molecule, one end (polar) being water soluble and the other being insoluble in water and soluble in oil. Such molecules tend to form a concentrated film at the interface between the water and the dirt, each molecule attaching itself at one end to the dirt and at the other end to the water, and hence tending to pull the dirt into solution.

There is much evidence that the micellar (colloidal electrolyte) form of soap must be present at the dilution used for washing. Nevertheless, many authorities maintain that detergent power derives from the long-chain fatty ion, which is also present.

As a practical matter, it should be emphasized that soaps used for household laundering usually contain considerable quantities of "builders" such as sodium silicate, phosphate, etc. There may also be present a fluorescent or substantive dye which adheres to the laundered cloth to give a whiter or brighter appearance. Likewise a percentage of carboxymethyl cellulose may be included in the product to inhibit redeposition of dirt on the cloth from the wash water. These additives contribute to the final overall appearance of the cloth and to the apparent detergent power of the soap. The suds are useful in indicating that sufficient soap is present to ensure detergent activity. The contribution of the suds to the actual detergent effect, while positive, is in some instances indirect. In some types of automatic washing devices, the suds must be controlled to lower levels for most efficient washing. Because bacteria can decompose soap easily, waste water containing soap does not impose the problems of water pollution commonly encountered with synthetic "hard" detergents (*see* DETERGENTS AND WETTING AGENTS).

Soap Materials.—Almost any fat can be used in making soap, but the principal requisite for a successful commerical product is an economical and proper balance of stocks to yield a soap that will exhibit the necessary soaplike properties over a wide range of conditions. Properties of a given soap (*e.g.*, sodium stearate) are evident only under certain conditions, as noted above. This characteristic behaviour necessitates the "blending" of fats to produce a widely applicable product. Thus, tallow is much used in making soap, but tallow alone will not yield a toilet soap that will give a copious lather over a wide range of temperatures in either soft or hard water. Therefore the tallow is commonly blended with a proportion of coconut oil, although palm kernel oil may be substituted. Various blends of oils and fats are used for laundry soaps, and almost every known fatty oil at one time or another has found its way into soap manufacture.

The most generally used stocks among the animal oils are tallow and grease; of the vegetable oils, coconut, cottonseed, corn, soya, palm, palm kernel, and olive are used. Fish and whale oil were used in making soap in increased quantities after the process of hydrogenation (*q.v.*) enabled them to be hardened to proper consistency and largely deodorized. Rosin (in saponified form) is an ingredient of yellow laundry soaps. Certain alkaline materials (builders) are almost universally present in laundry soaps. The most important are sodium silicate (water glass), sodium carbonate (soda ash), and various phosphates. These materials give increased detergent action and are not to be thought of simply as fillers, such as starch and barites, which are added to

reduce manufacturing costs. For saponification of the fats, large quantities of caustic soda are required by the industry, together with lesser quantities of caustic potash for soft soap manufacture. Ammonia, triethanolamine, and various organic bases are used to make special soaps.

Manufacturing Processes.—Soap is manufactured by the boiling, hydrolyzer, or semiboiling process.

Boiling Process.—The object of the boiling process is to produce neat soap in purified condition free from glycerol, the starting material for making bars, flakes, beads, and powders. The process is conducted in a series of steps called changes, and all the changes occur in the same piece of apparatus, the kettle (U.S.) or pan (British). The soap kettle is one of the largest pieces of processing equipment used by any chemical industry.

The first step begins with the introduction of the melted fats into the kettle together with some excess of caustic (soda) solution, which is added gradually. The whole mass is boiled with open steam from perforated coils within the kettle. A gradual emulsification occurs, the caustic solution reacting with the fat (saponification) to form soap and glycerol.

To separate the glycerol from the soap, the pasty boiling mass is treated with brine or salt. The contents of the kettle "salt out," or separate into two layers, the upper a curdy mass of impure soap, the lower an aqueous salt solution containing the dissolved glycerol. The basis of glycerol removal is the solubility of glycerol and the insolubility of soap in salt solution. The slightly alkaline salt solution, termed "spent lye," is run off from the bottom of the kettle and subsequently treated for glycerol recovery.

The grainy, curdy mass of soap remaining in the kettle after the spent lye has been removed contains any (usually traces) unsaponified fat that escaped reaction during saponification and also dirt and colouring matter present in the original oils. The "strong change," calculated to remove the last traces of free fat, is carried out by adding strong caustic solution and boiling for several hours.

The final stage (pitching and settling) transforms the soap into the neat form and removes the last traces of dirt and colouring matter. The soap, after the strong change, may be given one or more saltwater washes to remove free alkali, or it may be pitched directly following the strong change. In any case the open soap is partially "smoothed" by boiling with addition of water (or open steam condensation) until the concentration is attained at which the kettle contents separate into two, or sometimes three, layers. The upper layer is neat soap (kettle soap) of an almost constant composition for a soap from a given fat (approximately 70% soap–30% water); the lower layer is a nigre, whose composition varies between about 15% and 40% soap, depending on the "closeness" of the pitch. Since colouring matter and dirt (also salt, alkali, and metal soaps) generally are soluble in nigre but relatively insoluble in neat soap and because most of the impurities are dense and tend to settle, the nigre layer removes these impurities from the neat soap. The kettle boiling process requires from 4 to 11 days from the time the saponification starts until the neat soap is ready to be drawn off. Even today the complicated stages of the boiling process are usually conducted by the soap boiler using the appearance and taste of the soap as criteria for judging its condition. The utilization of the finished neat, or kettle, soap in making the final commercial product is described below under *Soap Products*.

Hydrolyzer Process.—The boiling process requires that individual batches of fat be treated in separate units (kettles). Continuous processes have replaced the older batch process by 50–75%. Where, in the kettle, alkali is used for saponification, in the hydrolyzer process the fat is "split" into fatty acids and glycerol by means of water at high temperature and pressure in the presence of a catalyst (zinc soap). The splitting reaction

$$\underset{\text{fat}}{(RCOO)_3C_3H_5} + \underset{\text{water}}{3HOH} \rightleftarrows \underset{\text{fatty acid}}{3RCOOH} + \underset{\text{glycerol}}{C_3H_5(OH)_3}$$

is carried on countercurrently, usually in a vertical column 50 ft. or more in height. The molten fat and water are introduced continuously into opposite ends of the column, while the fatty acids and glycerol are withdrawn continuously. The water, almost insoluble in fat at low temperatures, becomes soluble to the extent of 10–25% at 400°–480° F, the reaction being greatly speeded up by the solubility effect.

In about one hour a given unit of fat passes through the column and is 99% converted to fatty acids, which, as drawn off, are continuously distilled under vacuum to effect purification. They are then neutralized with a caustic solution (NaOH or KOH) containing the proper amount of water to yield neat soap phase. As in the boiling process, this phase constitutes the base material for further processing into bars, flakes, powders, pastes, or other products.

The operations necessary to obtain final products can be combined sequentially with the hydrolyzer to give a continuous flow from the original fat to the final marketable product, the whole sequence occurring in a matter of hours as contrasted with the 4–11 days required by the boiling process. The by-product glycerol is purified and concentrated synchronously with the fatty acid production.

Considerations of time, factory space, quality, and control of product characteristics contributed to the introduction of this process into the soap industry.

Semiboiling Process.—The semiboiling process may be thought of as ending when the saponification change is completed. The fat is saponified, usually in small quantities, as completely as possible by boiling with a caustic solution. The saponified mass containing the glycerol is run into frames for cooling and solidifying or, in the case of soft (potash) soap, is packed directly into containers. This process has the advantage of allowing, by water adjustment, the direct production of neat soap, middle soap, or, in some instances, nigre (liquid) soap.

Soap Products.—Hot neat soap phase from either the boiling or the hydrolyzer process forms the starting material for many products.

Framed Soaps.—These are usually made by pumping molten neat soap into molds, or "frames," to cool. The solidified soap is then cut and stamped into cakes. Such soaps contain about 70% soap to 30% water. For laundry purposes, builders such as water glass, phosphate, etc., are "crutched," or mixed in, before solidification.

Floating Soaps.—Formerly, most of these were made by crutching air into the neat soap before cooling. Rapid chilling or "freezer" processes are now in use. The molten neat soap is either aerated and then rapidly chilled or chilled to a semisolid condition and then aerated. The two procedures give bars of somewhat different lather and other characteristics.

Milled Soaps.—Most toilet soaps of better quality are made by the milling process. Originally developed in France as a way of allowing the cold incorporation of fine perfumes that could not withstand the heat of the crutcher, the milling process is now applied to the bulk of toilet soap manufacture. It produces a glossy, waxy bar that is characteristically smooth and has more pronounced qualities of lather and solubility than unmilled soap.

The most widely applied milling process requires that the hot neat soap first be reduced to ribbon or flake form. The molten soap flows between two hollow, rotating metal rolls, one warm, one cold. The warm roll spreads the soap into a thin film that solidifies and adheres to the cold roll. The film is removed in ribbons which are dried in an oven to about 12–16% moisture. After the dried, cooled ribbons have been broken into flakes, they pass into an amalgamator, where perfume, dye, and any special ingredients are mixed into them. The amalgamated soap then passes between successive polished metal (sometimes marble) rolls, which press the perfume and any other added ingredient evenly into the soap. The sheet of soap from the final milling roll is cut into ribbons and flakes and then subjected to pressure in a "plodder," a screw device operating in a cylinder where the flakes are forced together and cemented into a continuously extruded bar or cylinder of soap. The soap coming from the plodder is cut into lengths, which are then stamped into bar or tablet form and wrapped.

Flaked or Chipped Soaps.—Soap flakes are ribbons of dried soap broken into short lengths. The development of packaged soap flakes came about mainly between 1920 and 1930 and in the United States was concomitant with the introduction of small-scale, household, power washing machines, which created a great demand for soaps that were more soluble than the old bar soaps or chips cut from bars. By 1939, 0.002-in.-thick flakes were produced, compared with early products, which were of the order of 0.1 in. thick.

Neat soap forms the basis for soap flakes. The crutched soap, containing builder if desired, is run onto the rolls (*see* above, *Milled Soaps*), spread into a film or sheet, and removed in the form of ribbons. These are then dried to proper moisture (usually 5–15%), broken into flakes, and packaged. By proper control of moisture, fat stocks, and pressure, increased transparency is sometimes imparted to the flakes.

Granulated Soaps, Beads, and Powders.—Flaked soaps took a long step in the direction of a product of increased effectiveness in use. About 1926 occurred a new development, applying spray drying methods to neat soap. Early powders and granulated products were made by grinding flakes to the desired fineness, but such products when coarse were slowly soluble and when fine lumped and "balled" in water. When hot neat soap is sprayed into a current of heated air, the atomized soap particles dry and expand into bead or bubble form. The puffed particles, of spongy texture, exhibit a very high rate of solution and do not have the dusty quality of other types of powdered soap. Denser unpuffed particles may also be made by spray drying at lower temperatures.

Medicated Soaps.—Soap itself has germicidal power against some organisms, and many of the cationic synthetic detergents are strongly germicidal. Soap is used as an enema and as an emetic. Substances such as hexachlorophene are sometimes used in soap to suppress formation of the odorous compounds of perspiration.

Textile Soaps.—In the preparation of wool fabrics soap is required in three stages: scouring of raw wool to remove wool grease, scouring the yarns and cloth after oiling, and in fulling or milling. Soap is used for degumming raw silk; for cleansing rayon, silk, and cotton before and after dyeing; in the dye bath; and in printing. For all these purposes ready solubility is required, and hence soda soaps of low titre (*e.g.*, red oil, olive, corn) and potash soaps are preferred. Synthetic detergents have entered widely into the textile field because of their stability toward acid and hardness in water. They are used in scouring both cotton and synthetic fibres.

Shaving Creams.—Shaving creams are usually mixtures of potash and soda soaps of tallow and coconut oil. The cream is prepared by semiboiling methods. Bar shaving soaps and powders are of similar composition except for water content, which is kept at a minimum. Latherless or brushless shaving creams are not strictly soap at all but modifications of vanishing or cold cream formulas. In any type of lather, water is the principal beard-softening ingredient.

Metallic Soaps.—The term metallic soap refers to the fatty soaps of the alkaline earths and heavy metals. Their chief common characteristic is insolubility in water, hence their application (copper soap, aluminum soap, etc.) as waterproofing agents. The lubricating grease industry uses large quantities of calcium, aluminum, and other soaps to produce greases of various types, since another important characteristic of the metal soaps is their ability to gel in mineral oils. The demand for extreme pressure lubricants brought about the development of transparent, or clear, greases which are usually prepared by addition of aluminum soap, alone or in combination with other soap, to oil of the desired character.

SOAP PLANTS, the name given to numerous herbs, shrubs, and trees that contain the poisonous glucoside saponin. Various parts of such plants form a lather in water and may be used for cleansing purposes, as the soapbark (*Quillaja saponaria*) and the soapberries (*Sapindus* species). Other examples are the soapwort, or bouncing Bet (*Saponaria officinalis*), and the cowherb (*S. vaccaria*).

In the southwestern United States various plants called *amole* by the Indians are similarly utilized, especially the small agave (*Agave heteracantha*) and the soaproot (*Chlorogalum pomeridianum*). Other soap plants of the western United States are *Zygadenus* species and the sand lily (*Leucocrinum montanum*).

SOBAT, a river of northeast Africa, enters the White Nile (Al Bahr al Abyad) south of Tawfiqiyah, Sudan. The Sobat basin includes the southwest Ethiopian Plateau and the marshy eastern part of the southern Sudan depression with indeterminate limits to south and north. The Sudan-Ethiopia border from 6° 10′ N to 8° 40′ N is marked by the Sobat's tributaries, the Jokau, Baro Pibor, Akobo, and Kaia rivers. The Sobat is about 220 mi. (354 km.) long from the confluence of the Baro and Pibor. Including its longest tributary, the Baro, the distance from source to mouth is about 460 mi. (740 km.). The Baro rises in Ethiopia at a height of 7,000 ft. (2,134 m.); it descends rapidly from the plateau, dropping 3,000 ft. (900 m.) in 45 mi. (72 km.), and passes through a narrow gorge 3,000–4,000 ft. (900–1,200 m.) deep. Below the gorge the Uaddessa joins the Baro from the north. Before Gambela is reached the river begins its course across the plains. It enters the Sudan at its confluence with the Khawr Jokau. On the north bank, 15 mi. (24 km.) downstream, lies the Khawr Machar which acts as an overflow channel into the Machar Marshes during the flood season. The Pibor drains from the south a vast area of indeterminate drainage reaching almost to the southeast extremity of the Sudan. Its main tributaries, the Gila and the Akobo, flow off the Ethiopian Plateau from the east, the Gila by a series of cascades through a break in the mountains, while the Akobo joins the Pibor at Akobo. The Sobat flows northwestward for 180 mi. (290 km.) from Nasir in a bewildering series of meanders to its confluence with the White Nile; by road Nasir is just over 100 mi. (160 km.) from the confluence. Downstream from Nasir the Sobat receives two sizable tributaries from the south: Khawr Nyanding and Khawr Ful Lus, joining the river 120 and 15 mi. (193 and 24 km.), respectively, above its mouth. Approaching the White Nile the river becomes deeper and narrower, flowing between definite banks. At its mouth it is about 400 ft. (122 m.) wide with a depth varying with the season of from 18 to 30 ft. (5–9 m.). Its discharge when in flood averages 27,192 cu.ft. (770 cu.m.) per sec. (October–November), ponding back the White Nile; the whitish sediment brought down by the Sobat accounts for this name. At low-water stage in April the White Nile flows back up the Sobat as far as Khawr Ful Lus. The Sudan government planned to construct a dam on the Baro as part of the Equatorial Nile Project (*see* NILE), with the aim of developing storage of the White Nile water nearly to its maximum.

The Sobat river system is navigable during the period June–December, via the Baro for shallow-draft steamers to Gambela, and up the Pibor to Pibor Post for small craft. Vehicles can cross the Sobat by ferry just below Khawr Ful Lus. The inhabitants of the drainage basin are Nilotic peoples including the Dinka, Nuer, Shilluk, and Anuak. The dry season pastures (Dinka, *toich*) provided by the fall in river level are a basic factor in the life of these cattle-owning people.

An Egyptian army expedition ascended the Sobat for a short distance in 1841. Nasir was founded as an anti-slavery patrol post in about 1875. Exploration above Nasir was completed by J. B. Marchand who on his return journey to France from Fashoda ascended the Baro to the foot of the Ethiopian Plateau; by the Italian V. Bottego; and by numerous British army officers (such as Capt M. S. Wellby and Brig. Gen. H. H. Austin) and administrators at the beginning of the 20th century. (H. R. J. D.)

SOBIESKI, JAN: *see* JOHN III (Jan Sobieski).

SOCAGE, a type of feudal land ownership whereby a freeman held a fee simple estate as tenant of a lord in return for render-

ing periodic agricultural or economic services. With the decline of feudalism and the rise of a money economy, "free and common socage" became the most desirable form of land tenure, and on the restoration of Charles II in 1660 almost all species of tenure were converted by statute into socage tenure. (*See* REAL PROPERTY AND CONVEYANCING, LAWS OF.) Free and common socage was also the most common tenure by which the king granted lands in the North American colonies. Since tenure has no modern significance in Anglo-American property law, socage tenure is no longer important; if its semblances are retained, it is for nonlegal reasons.

Although socage developed under Norman feudalism in England, it is Anglo-Saxon in origin. The term is derived from the Old English word soc or soke and is frequently associated with sac, in an alliterative jingle ("sac and soc"). The precise meaning of both terms is uncertain, but they refer to the district in which a lord may hold court, to the right of a tenant to make suit in such a court, and to his duty to use the court. The "sokemen," or persons holding by socage tenure, were a class of tenants midway between the military or chivalrous class and the bond tenants or villeins. Although freemen, they performed many agricultural services similar to those performed by the villeins.

If a freeman had to own land under the theory of feudal tenure, socage was the least objectionable form. Minors inheriting socage lands were not, as in military tenure, wards of the lord who held the land but came under guardianship of the nearest relative who could not inherit the lands, and this guardian, unlike the lord in a wardship, could not keep the profits during minority but had to account to the heir for them. Neither, under socage, could the lord or guardian "sell" the minor heir in marriage for his own personal profit. As in the case of military tenure, however, the death of the owner required the heir to pay the lord a relief to claim his inheritance.

At an early time the services due the lord were commuted into fixed money payments called "quitrents." These at first represented the economic value of the land, but with the long continuous fall in the value of money they became so insignificant as not to be worth collecting. Sometimes the services were purely nominal as the result of gifts to younger members of the family, to friends, or as the result of a sale for a capital sum with a nominal quitrent reserved to preserve the form of the tenure.

The 1681 Charter of Maryland granted to Lord Baltimore lands to be held in free and common socage yielding to the king as lord "two Indian arrows of those parts to be delivered every year on Tuesday in Easter week." The feudal service attached to the grant of Pennsylvania was the delivery to the king of two beaver skins annually.

In some American colonies, the king permitted the grantee in socage to establish his own manor, that is, to regrant portions of the land to tenants in return for an annual rent, although this could not be done in England after 1290. Thus some property owners in Pennsylvania rendered to the members of the Penn family a red rose at midsummer, a service that is now continued only for ceremonial reasons. In New York and some other parts of the North American colonies, those holding grants from the king sought to impose substantial quitrents on their grantees. Thus even after the Revolution the Van Rensselaer family granted lands on the upper Hudson to a settler "forever" upon a yearly rental of a certain number of bushels of wheat. So distasteful was this feudal concept that these quitrents contributed to uprisings such as Bacon's Rebellion in Virginia in 1676 and to some major antirent disturbances in New York in the mid-19th century.

(A. DM.)

SOCCER, the name given in the United States and Canada to the game called, with a few minor exceptions, football or association football in all other parts of the world. For a description of the game as played outside America, *see* FOOTBALL: *Association Football (Soccer)*.

Many different stories are current about where the first games of soccer were played in America. A marker on the Common in Boston, Mass., refers to the fact that the game was played there. There is little doubt that the first intercollegiate "football" game between Princeton and Rutgers was actually a version of soccer, and it has been fairly well established that the game was introduced into the United States by the British.

Like American football, soccer is played by two teams of 11 men each, employing a round leather- or rubber-covered inflated rubber bladder slightly larger than a volleyball and slightly smaller than a regulation basketball. It is called the booting game for good reason: only the goalkeeper is permitted to touch the ball with his hands while it is in play.

The main propulsion of the ball is given by a player's foot, although he can use any part of his body except his hands and arms to trap, deflect or project the ball. Heading the ball is considered a major movement in the game.

Should a player other than the goalkeeper handle the ball deliberately or unintentionally, a penalty is called against him and the opposing team is permitted a free kick. When the infraction occurs in the penalty area of the defending team, the attackers are allowed a penalty kick from a point 12 yd. out and directly in front of the goal.

A regulation game in soccer consists of two halves of 45 minutes' duration each. In the event that a 90-min. game cannot be played for a specific reason, the time may be shortened, but the halves still must be equal. Some college conferences and scholastic leagues play their games in equal quarters rather than halves, but no regular games last longer than 90 min. unless there is a provision for overtime play in order to determine a winner.

Play.—The maximum length of a soccer field or pitch, as it is known, is 130 yd., with the minimum set at 100 yd.; the maximum width is 100 yd. with the minimum 50 yd. The markings of the pitch include two touch lines (the length of the field) and two goal lines (the width of the field) to make a rectangle. In addition there is a midfield line across the width of the field with the centre kickoff circle (10 yd. in diameter). Before each goal is a penalty area 18 yd. long by 44 yd. wide. Inside the penalty area and also before each goal is a goal area 6 yd. in length and 20 yd. in width. The two goal posts are 8 yd. apart supporting a crossbar 8 ft. off the ground. Normally nets are required to be attached to the goal posts and crossbar and extending behind the goal.

The penalty kick area is denoted by a small (solid) circle directly in front of and 12 yd. from the goal. Quarter circles of 1-yd. radius are marked at each corner for the corner kick, which is given when the defending team last touches the ball before it goes over the defending team's goal line outside the goal. Corner flags, preferably of some bright colour, are placed in the four corners of the field.

To score a goal, the whole ball must pass over the goal line between the two goal posts and under the crossbar, either on the ground or in the air, without being carried, thrown or motivated by arm or hand of an attacking player. If a defending player accidentally kicks or deflects the ball into his own goal, it counts as a goal for the opposing side.

Three types of kicks are awarded for rule infractions including penalty kick and direct free kick from which goals can be scored directly. In order to score on an indirect free kick the ball must be played by another player before entering the goal.

When a ball goes over the touchline, it is awarded to the opponent of the team that last touched the ball before it went out of bounds. A throw-in is taken at the point where the ball went over the touchline. It is the sole instance during a game when a player other than the goalkeeper is allowed to handle the ball. The colleges have amended the throw-in rule to make it a kick-in.

The offside rule is an important rule of the game. A player is offside when there are not two defending players nearer the goal than himself at the time the ball is passed to him, with the following exceptions: from a goal kick; a corner kick; a throw-in; when he is behind the ball when the pass is given; when the ball comes from an opponent; when he is in his own half of the field.

One of the American deviations from international rules is that substitution of players is permitted in American soccer. However, the different governing bodies and sectional leagues have varying limits on substitutions. On the whole, the deviations from the international rules are rather few, which is one of the reasons why

soccer lends itself easily to international contest.

Competition and Organization.—Soccer is a relatively simple game to understand, the basic rules being neither complicated nor difficult. It is also an exciting game, with play going on continuously in the open. Compared with American football it is inexpensive to support, and there are no special physical requirements for the participant, hence wide participation is possible. While the popularity of soccer in America has not always been great, it is still expanding in schools and colleges, where it is a seasonal sport, played for about three months in the autumn.

The season of amateur and professional soccer runs for approximately ten months with a layoff during the summer. In certain areas competition is halted during the winter because of poor field conditions.

In addition to the various league and state competitions, three major national tournaments attract entries. The National Challenge cup competition for the Dewar trophy is the open tourney in which professional and amateur teams compete. The event was first held in the 1913–14 season and regularly thereafter. In the 1923–24 season, entries for the National Challenge cup became so numerous that it was decided to inaugurate the National Amateur cup competition to be restricted to amateur teams and amateur players. The National Junior Challenge cup, limited to junior teams, began in the 1934–35 season, but the final game between eastern and western sectional champions is not always played.

The United States Soccer Football association (U.S.S.F.A.), organized in 1913 and successor to other predecessor groups, is the governing body of the sport in America. This includes amateurs and professionals, who are allowed to play side by side on the same teams without any change in status. College and school groups have their own organizations and are merely associate members of the U.S.S.F.A. Leagues and state associations of amateur and professional groups are direct affiliates of the U.S.S.F.A.

Only one organized professional league is recognized, the American Soccer league, which operates chiefly along the eastern coast and includes New York, Newark and Elizabeth, N.J., Philadelphia and Baltimore. In 1960, the International Soccer league was formed to include visiting foreign teams and a New York side.

In the late 1920s and early 1930s, a professional soccer player was able to earn money enough so that he could devote full time to the game. Currently, however, even the highest paid professional cannot support his family by playing. Whereas European players devote regular days and hours each week to practice, few teams in the United States hold regular drills. A team designated to represent the United States in international competition usually has opportunity for no more than one or two practice games, which is reflected in the poor showing of United States teams in such competition. Further, few clubs, leagues or associations have the personnel to conduct programs to promote development of young players.

Soccer in the United States is an amateur rather than a professional sport. Few soccer teams have their own stadiums; most of the big international games are played in baseball parks or municipal or school stadiums. For the most part, however, regular games are played in parks or on open fields. (M. Mi.)

SOCHI, a town and resort of Krasnodarskiy (Krasnodar) Kray of the Russian Soviet Federated Socialist Republic, U.S.S.R., stands on the Black Sea coast, at the foot of the western part of the main Caucasus range. Pop. (1959) 126,779. The town now extends (administratively) for about 50 mi. (80 km.) along the coast from Lazarevskoye in the north to the border of the Georgian S.S.R. in the south. The presence of hot mineral springs and the warm climate (January average 6.1° C [43° F], July average 22.8° C [73° F]) have made it a popular holiday and health resort. It has 6 tourist centres, motels, and over 50 sanatoriums. Sochi is on the main Tuapse–Sukhumi railway and has passenger vessel connections with other Soviet Black Sea ports. There are a number of food-processing industries. (R. A. F.)

SOCIAL ANTHROPOLOGY, a social science concerned with the comparative study of human societies. Sharing this aim with sociologists, many social anthropologists regard themselves as sociologists of a specialized kind. However, social anthropology has dealt primarily with what are known as simpler, primitive, preliterate peoples, while sociology has stressed study of more advanced peoples. This division has tended to disappear as social anthropologists investigate advanced Oriental and Western societies, and sociologists move out to study the development of formerly primitive societies. Social anthropologists usually study small communities such as villages or special groups in factories, camps of displaced persons, or special aspects of social life such as kinship. But both disciplines share and contribute to a common theoretical framework. Social anthropology uses above all an intensive type of inquiry that ordinarily involves living among the people to be studied, learning their language, and closely observing their day-to-day activities. Discrepancies between word and act are often of great importance to the social anthropologist. So closely may he become involved that he may engage in participant observation; that is, he cooperates with the people by engaging in their activities himself—going on a fishing expedition, taking part in a religious rite, keeping their tabus, exchanging property with them as if he were a member of the society.

It has increasingly come to be recognized that the terms "society" and "culture" refer to different aspects of the same basic human actions and relations. "Society" and "social anthropology" emphasize the human element—interpersonal and intergroup relations. "Culture" and "cultural anthropology" lay more emphasis on creative achievement, the objects and ideas that are brought into being and transmitted from one generation to another. Cultural anthropology tends to be the wider, embracing, for instance, simple technology and linguistics as well as ethnography and investigation of social structures. But the emphases shade into one another and there is a large area of common ground. Anthropological opinion is not unanimous on this point. But the essential unity in major fields of interest is shown, for example, by the occasional use of the conjoint term "cultural/social anthropology."

Modern social anthropology is characterized by theoretical studies (of social structures and processes) that are comparative, at least by having primitive societies as one pole of reference. It may be distinguished from the more descriptive field of ethnography, though much published work in social anthropology also contains descriptive material. The subject owes much to theoretical analyses by sociologists, including the older European writers E. Durkheim, M. Weber, V. Pareto, and M. Mauss (*qq.v.*), and such modern U.S. contributors as K. Davis, R. Merton, and T. Parsons. Less has been gained from psychology, though the theory of the family and kinship have been influenced by the work of Freud. Major developments of social anthropology early in the 20th century were due to W. H. R. Rivers, A. R. Radcliffe-Brown, and B. K. Malinowski (*qq.v.*) in Great Britain; A. L. Kroeber, R. Linton, A. Goldenweiser, and R. H. Lowie (*qq.v.*) in the U.S.; and R. Thurnwald in Europe. Later developments were more international; *e.g.*, the work of C. Lévi-Strauss in France. Though originally primarily a Western interest, by the 1960s social anthropology was enriched by Asian, African, and other scholars.

In the early years attention focused on structural and functional studies of family, marriage, kinship and local grouping, magic and witchcraft. In the second half of the 20th century, while kinship studies remained the core, social status and power attracted attention in the investigation of political and legal systems, and systems of social stratification. There was more concern also with systems of ritual and religious ideas. Interest shifted from African peoples, who had occupied social anthropologists for a quarter of a century, to peoples in India, Southeast Asia, Latin America, and Oceania. By the 1960s a more dynamic approach was apparent, particularly in problems of social process (as well as structure). Analyses of social change were no longer considered a separate branch of the subject, being incorporated in most studies. Attention was paid also to the significance of the time dimension in the maintenance and replacement of social units and institutions. Much greater use was made of quantitative data, as in studies of family and domestic group relations, marriage, divorce, and economic transactions.

Social Structure and Organization.—The basic data for social anthropology are usually defined as social relations arising from

the necessities of living in society. Social relations have regularities or patterns shown by repetition—as when a man plays with his children every evening after he comes home from work. These relations tend to compose a system, being linked with, and to some degree determined by, others. So a man's regular relations with his children in play are tied in with his relations with them at meals and in the house generally, and depend in large part on his relations with their mother. They may also depend on his economic relations—as when he is forced to go away from home on business—or on his legal relations—as when a court awards him custody of his children at divorce. The main elements of the interdependent system of social relations, looked at somewhat abstractly, form the social structure.

Social structures are sometimes stated (as by E. R. Leach and Lévi-Strauss) to be ideal or formal models representing the main principles of a society or social system. Less formally, social structures may be regarded as comprising the more permanent groups and other continuing features of the social system (E. E. Evans-Pritchard), the network of social relations of the system (Radcliffe-Brown, F. R. Eggan), or the crucial interdependence of role relationships in a society (S. F. Nadel). These, however, are all linked concepts, since the regularity, interdependence, and permanence of social relations depend largely on the ideal type laid down by the society, and perception of all this involves considerable abstraction of formal qualities by the observer.

Social structure is like the anatomy of the society—it provides its major shape. But the conduct of individuals varies; some follow the rules laid down and others do not. Not every man abides by the legal and moral rules of marriage—nor does every man or woman marry. Some fathers make generous provision for the education of their children and try to guide their social development. Others allow them to fend for themselves. In all fields of social action different arrangements by individuals arise from choices they make between alternatives. The total body of such actions can be termed social organization.

Linked with these concepts is the notion of social values, the system of preferences that govern action in any society. By adhering to conceptions and principles embodied in the system of social values members of the society maintain their social structure.

Structure of Primitive Societies.—The most obvious distinction of a primitive society is its size—it may consist of only a few hundred or a few thousand people, very rarely hundreds of thousands. Though demographic studies have been shown to be important for structural analysis (M. Fortes and others), size alone is not the most important factor in the structure of a primitive society.

In such a society almost all interpersonal relations are face to face—except where Western influence has introduced written communication. Moreover, for technical and social reasons, people are apt to move about much less. Hence, any one person is apt to have relationships with fewer people than in Western society and those relationships are likely to be more permanent. Almost every relationship is between people already acquainted; the impersonal day-to-day contacts of Western society—as with a sales assistant or a government official—are unlikely to occur.

This factor of proximity—expressed formally in terms of neighbourhood associations and local groupings—is extremely important in social relations. The units of household, homestead, hamlet, village, and urban ward vary greatly in different societies. They serve as a basis for economic and other cooperation; they tend to determine the character of kin grouping by virtue of the property and other rights usually associated with them. In a primitive society, the range of occupations and special social activities is much narrower than in Western society; there is far less differentiation of roles. Most of the people are primarily engaged in obtaining food with fairly similar technical equipment. This sharply limits the types of relationship possible for a given person. But the people with whom one is in contact may play several roles; relationships are many-stranded. The same person may be father, war leader, judge, economic boss, teacher, and priest.

This many-stranded quality confronts the social anthropologist with a problem of disentangling for analysis (sometimes arbitrarily) such categories as economic, political, legal, and ritual relations. The overlap leads the anthropologist to emphasize interdependence; *i.e.*, to seek the function of the relationships in any one field in maintaining the total pattern of the society.

In any society, people arrange themselves in groups—families, villages, clans, professional associations, age sets. In a primitive society, groups tend to be closed rather than open; *i.e.*, most groups recruit through birth, and membership is compulsory. In a society of this kind a man does not normally belong to groups having purely voluntary membership, though in some communities clubs and secret societies may be recruited on such a personal basis (*see* SECRET SOCIETIES, PRIMITIVE).

In a primitive society more behaviour concerns prescribed group membership than in Western society. Since there are fewer differences in specialist skill and interest, principles of age, sex, neighbourhood, and kinship are the common bases for group formation. The people are very dependent on, and rarely able to change, group membership; conformity to wishes and standards of others in the immediate environment is important to well-being, even to survival.

The rate of social change (barring outside influences, natural disaster, economic penetration or conquest) is slow, though all primitive societies have not been static, as has sometimes been assumed. But when a small primitive society comes into contact with Western civilization, the changes are bound to be rapid and may be catastrophic. New techniques alter patterns of work and cooperation; new avenues of employment open; the introduction of money greatly accelerates exchange, provides a more general measure of value, and wealth becomes more easily storable. Missions, government, and other development agencies introduce new rules and values, and affect the institutional life of the people. Traditional social controls lose force and social disintegration often results. In extreme cases (such as African shantytowns) crime may increase greatly. Yet some societies successfully raise material levels of living and increase the scale and complexity of their economic and political organization without radical alteration in morale. Some societies react with new social and ritual forms, such as the Ghost Dance of the North American Indians, with its conscious and organized revival of native culture; or cargo cults of New Guinea, ritual attempts to secure trade goods that are in the hands of Europeans (*see* NATIVISTIC MOVEMENTS). These have led to far-reaching and subtle modifications in social structure that are not simply mixtures of primitive and civilized ways; they are fresh social phenomena, new structures, demanding special study and new techniques of approach.

Sex and Age Grouping.—All societies make distinctions by sex and age. In primitive societies women are primarily responsible for young children and for most domestic tasks, while jobs that involve heavier work, greater distances from home, or violence (hunting and fighting) are male tasks. Formal control of internal group affairs and of external relations is almost entirely in the hands of men, though women may exercise great informal power. Among the Iroquois, women had the power to nominate and depose chiefs, but only men could hold the office. Queens or female chiefs, as among the Lovedu tribe in the Republic of South Africa, generally lack real power, or are symbolically equated with men. Division of labour by sex varies greatly; in one society men till the ground, in another they leave this entirely to women. Violation of local rules may cause mirth or abhorrence; the tasks of one sex are often ritually forbidden to the other. Invariably, as in Western society, sex is symbolized in differences of dress, ornament, and etiquette. It may be emphasized by ritual procedures or in myths.

The principle of seniority is equally used for social distinctions. In a few societies old people are regarded as a burden, but almost invariably old age is highly respected. Where there is no writing and where skills and cultural heritage alter little through the generations, old men are the obvious repositories of wisdom and experience. In its extreme form, the respect for the aged becomes gerontocracy (*q.v.*), rule by old men. In such societies, old men

keep for themselves special privileges, often including prior rights to marry younger women, and their position is often backed by magical knowledge and tabu. Sometimes the age principle is formalized in a system of grades. The change in status from child to adult is marked by a ceremony of initiation (usually including an ordeal). Those initiated together form a group (*see* AGE SET) with special rights and obligations. Ritual occasions, including formal transfer of insignia, may mark the movement of a group of age-mates from one status to the next. Even where no age set exists, the principle of seniority is usually of great importance.

Kinship.—A major contribution of social anthropology has been a refinement of understanding it has brought to the study of kinship (*q.v.*). Kinship is the social recognition of real or putative biological ties formed by procreation and marriage. The continuity of any society depends on the procreation and training of new members. The kinship system provides legitimacy for the procreation of children; responsible persons and social units undertake their care and training and place them in a defined position in society.

The minimum kinship unit is the elementary (nuclear, individual) family, consisting of father, mother, and children. Almost every adult is a member of two such families, called by W. L. Warner the family of orientation (that into which one is born or adopted), and the family of procreation (that in which one becomes a parent). The interlocking of these families creates a complex framework of kin relationships, consisting of consanguineal ties (by blood) and of affinal ties (by marriage). Adoption is the simulation of consanguineal ties. Most human societies use kinship in ordering economic, political, judicial, and ritual affairs.

The study of kinship in anthropology began with work in kinship terminology (*q.v.*) by L. H. Morgan. He and his contemporaries sought to classify systems of kinship terminology as stages of human evolution, equated with levels of political and technological development. Where they thought terminology was inconsistent with existing social structure, they supposed a previous state of society that would fit. Lowie, Radcliffe-Brown, and Malinowski attacked this evolutionary approach, insisting on analysis and comparison of contemporary societies to establish general principles. Speculation about origins of human institutions, that provided the main drive for the beginning of anthropology, was abandoned as unprofitable.

It is now generally recognized that kin terms cannot be understood without reference to the total pattern of kin behaviour. Nevertheless, terminologies provide important clues to the structure of a society. They reveal how people classify their kin, reflect the system of descent groups, and provide linguistic symbols for much social behaviour.

The concept of the family as a kinship unit is clearly separated from that of a domestic unit such as a household, though these units overlap in fact. Statistically the elementary family is frequently the residential norm, occupying a separate dwelling. But in many societies, as in Malaya, a young couple begin married life in one of the parental households rather than in a new home (neolocal residence) of their own. Residence with the groom's family is termed patrilocal or more correctly virilocal; with the bride's family, matrilocal or uxorilocal. Kin in such a domestic unit are called an extended family (expanded family). A household of two or more siblings, their spouses, and children may be termed a joint family—fraternal or sororal as the case may be. In some societies, such as rural Turkey, the two types of structure often merge on the death of the parental head. Modern social anthropologists increasingly realize the significance of the developmental cycle in the structure and operations of these domestic groups.

The study of descent groups is crucial in modern social anthropology. Born (or adopted) into a family, one may belong also to a wider descent group. In defining this kin group, one or both parents may be relevant. Descent reckoned through one parent only is unilineal; such a descent group is a lineage. A patrilineage consists of male descendants (through males) of a common ancestor, together with their sisters and daughters; a matrilineage consists of female descendants (through females) of an ancestress, together with their brothers and sons. A lineage is normally corporate, its members exercising rights in common and collectively subject to obligations. A lineage may comprise any number of generations, but commonly is traced through five to ten. Genealogical connections of a large lineage often are inconsistent, even obviously invented and lacking historical validity. Lineage structure may be regarded as the result of a branching process, as when two or three founders of small lineages are represented as brothers. The groups thus comprise a single larger lineage in which the smaller descent groups are segments; this segmenting process may be very extensive. Evans-Pritchard, Fortes, Leach, A. W. Southall, J. Middleton, and others have shown that many political and ritual relations in a primitive society may depend on this segmentary structure.

In many societies the lineage is exogamous; *i.e.*, a man cannot marry a woman of his own lineage, and marriages then set up relationships between lineages. The structure of patrilineal societies (*e.g.*, Nuer, Tallensi, Tikopia), where a man belongs to the group of his father, differs markedly from those with matrilineages (*e.g.*, Nayar, Trobriands, Hopi, Dobu), where a man belongs to the group of his mother's brother (*see* DESCENT, SYSTEMS OF; MATRILINY).

The prevalent pattern of residence greatly affects the operation of the unilineal principle. Among the Tallensi (*q.v.*) households under brothers or brothers' sons are usually adjacent; households in one area belong to a larger lineage segment; and so on, reflecting the lineage structure. Among the Nuer (*q.v.*) the fiction of localized lineages is found, although men often live with matrilateral or affinal kin. In matrilineal societies the problem is more complex. All the men of a lineage may live together, but their children belong to the lineages of their mothers. In the Trobriands, this difficulty is met by having sons join their mother's brothers on adolescence. If all the women of a lineage live together, no man of the lineage may be present to direct affairs—unless, as among the Hopi (*q.v.*), brother and sister normally live in the same village. Among the Yao of Nyasaland this problem is met by allowing the eldest brother of each set of sisters (sorority group) to take his own wife to live with his sisters, so that he can take charge of their affairs. Among the Dobu of the D'Entrecasteaux Islands couples alternate residence between the lineage-village of the husband and that of the wife. Among the Nayar (*q.v.*) husbands only visit their wives; the joint households contain brothers, sisters, and sisters' children by their visiting husbands. Here, as often, lineage members other than the joint family do not live adjacently, yet maintain coherence through common rights, duties, rituals, and symbols.

The word "clan," often vaguely used in older literature, usually means either a group of people claiming unilineal descent from a common ancestor but unable to give a precise genealogy, or (as G. P. Murdock suggested) a compromise kin group with residential unity. In the past the clan (*q.v.*) has been described as an exogamous unit (as it often is), but this strict definition is unnecessary. The word is now confined to unilineal descent groups although the Scottish prototype is bilateral.

In some societies both matrilineal and patrilineal descent are recognized for different social purposes. This is known as double unilineal descent. Thus among the Yakö of Nigeria (as C. D. Forde showed) the household and the farming group are based on patrilineages; matrilineal groups, although not residential, are of great importance in the ritual and political system. Under Western influences larger kin groups tend to break up as more individual rights are asserted. A. I. Richards and Fortes have shown for Bemba and Ashanti (*qq.v.*) that in matrilineal systems fathers tend to take over traditional functions of mother's brothers.

By the 1960s attention was directed to nonunilineal (ambilateral or ambilineal) systems that allow a tie through either mother or father as a basis for lineage. Among the Maori (*q.v.*), R. W. Firth showed that one's descent group may be his father's or his mother's according to his place of residence and maintenance of land rights.

Many societies have no specific descent groups. Kin groups exist, but differ for each set of full siblings. Though not forming a distinct group for any other purpose, a man's personal kin all may be held responsible for his offenses. Among the Kalinga of

Luzon, responsibility for homicide theoretically includes the offender's third cousins (in practice only second cousins).

Descent should be distinguished from inheritance of property and succession to office. Some kinds of property may pass patrilineally in a matrilineal society, or a sister's son may succeed to an office in a patrilineal society. But in societies with no clear-cut descent groups, succession and inheritance tend to be patrilineal, as most authority goes through men.

Though only one side of the family may determine descent-group membership, close ties are maintained with all who marry out of a group and their offspring; keen interest is taken in their welfare. Within any body of kin the principles of generation or kinship grade, and of solidarity of the sibling group, are important regulators of behaviour.

Marriage.—All societies distinguish between casual sexual relations, or cohabitation, and a formal union to establish a family. Several forms of union are often recognized in the same society (*see* MARRIAGE, PRIMITIVE).

Marriage generates a relatively permanent relationship between kin groups through common interest in the partners and in the offspring. Very often such a relationship between families is held inappropriate within a fairly large group, a clan, lineage, or village; such a group is then called exogamous. Exogamy (*q.v.*), by ensuring social links between potentially hostile groups, performs an extremely important integrating function. Conversely, the extreme case is that in which marriage outside a specific group is forbidden. For this the term endogamy (*q.v.*) is used and also more loosely for a tendency to marriage within a group. Endogamy is apt to characterize religious and ethnic minorities in civilized societies. In India, every small subcaste tends to be endogamous, on ritual grounds.

Strict endogamy is rare in primitive societies, but rules specifying the group from which a man must or should choose his wife are extremely common. It is often felt that an affinal tie between two groups should be preserved generation after generation. In unilineal societies this is done by a rule of cross-cousin marriage, by which a man takes his wife either from the group to which his father's sister went or from the group from which his mother came. (He may also give his sister in marriage to a man of this group.) As examined by Lévi-Strauss, Leach, and G. C. Homans with D. M. Schneider, such preferential rules support the stability of relations between groups.

In all societies the formal beginning of a new marriage is marked by ceremony; gifts are exchanged even if only food. In many societies, where groups of men hand over women, bride-price or bridewealth (*q.v.*) is paid; *i.e.*, the groom's side gives far more than the bride's. Sometimes dowry is paid with the bride. These gifts may continue as annual harvest payments, as in the matrilineal Trobriands, where a man is compensated for caring for the children of his wife's lineage.

Monogamy is common in all types of society, and polygamy is normally the exception, even where it is the ideal. But many societies permit more than one wife (polygyny) and a few permit more than one husband (polyandry). Each usually is a separate marriage, though sometimes with a minimum of ceremony. In polyandry the co-husbands are usually brothers, as in parts of Tibet, or else do not reside with their wife, as among the Nayar who practised both polygyny and polyandry.

In all societies unregulated extramarital intercourse with a wife is felt to be a wrong—at least to the husband. Reaction to adultery varies from mild claims for damages or divorce to killing both parties. But some kinsmen—a husband's unmarried younger brother or, as in the Trobriands, a brother's son—may be privileged, or special license is allowed on ritual occasions. Premarital intercourse is commonly condoned; but premarital pregnancy is serious, since it threatens to create an illegitimate member of society with no defined position.

Most societies recognize divorce, though in some it is almost unknown. Plausible attempts have been made to relate divorce rates to descent-group structure, to the structure of the household, and to amount of bridewealth, but no adequate theory has yet been found if only because the definition of marriage and of divorce in different societies makes comparison of the stability of marriage very difficult.

Rules against incest are found in all known societies; they should not be confused with exogamy. To forbid marriage within a specific group is not the same as a universal rule against sexual intercourse with close kin, particularly those in one's elementary family. Incest is widely thought to carry supernatural penalties (to be a sin); sometimes, as in Tikopia, these are almost the only penalties.

Status and Stratification.—Status is the social position an individual holds, with attendant rights and duties. The word implies stratification on a vertical scale. The spatial analogy covers several meanings. A man may be said to occupy a high position when he is able to control, by order or by influence, other people's conduct; or when he derives prestige from holding important office; or when his conduct has earned the esteem of his fellows. Relative status is a major factor determining the behaviour of people toward each other; and competition for status seems to be a prime pursuit.

One's status varies with social context. For example, the position of a man in his kin group helps determine his position in the community. Among the Hopi (as Eggan showed) the lineage, although unnamed, contains the mechanism for transmitting rights to land, houses, and ceremonial knowledge and is thus vital for personal status. Among the Tallensi (Fortes stated) a mere lad who (having lost his father) is head of a household counts as an elder; a middle-aged man still under his father's roof is formally a child. Status may be governed by occupational considerations; thus in Negro Africa blacksmiths commonly form a separate group of low status. In the Hindu caste system, sweepers are at the bottom of the scale because they handle human excrement.

Status is closely correlated with etiquette and morality, and in many societies rises with the liberal use of wealth (*see* POTLATCH). C. A. du Bois stated that manipulation of the wealth-status system (among the Alor islanders) often demands great individual effort, aggression, chicanery, and an excellent memory.

Social classes are groups arranged in a hierarchical status system; class members interact mainly within their own group and to a lesser degree with those of higher or lower status. While classes are rare in primitive societies, some kind of stratification is common. Even an age-grade system, as in many East African societies, may resemble a class structure. In some societies, clans or lineages may be ranked generally as aristocrats and commoners, or graded from a royal clan to clans that are stigmatized for lowly occupation or slave origin. True class systems obtain in the West African emirates, with urban capitals from which (as Nadel showed) a ruling class, different in dress, speech, etiquette, and morality, dominates a semipagan peasantry. Most striking is the caste system of India analyzed by S. C. Dube, M. N. Srinivas, F. G. Bailey, K. Gough, A. C. Mayer, M. Marriott, and others. In Hindu villages there are usually members of a number of small endogamous groups (subcastes) based on traditional occupations, arranged from Brahmans to Untouchables, though the exact order of the middle subcastes is not always agreed on by all parties concerned. Contact with a person of lower caste (such as eating or drinking from his hands, bodily contact) pollutes one of a higher caste and necessitates ritual purification. Escape from caste is very difficult, though Western influences have tended to loosen some rules and urban life allows latitude to many individuals (*see* CASTE [INDIAN]).

Economic Relations.—Economic behaviour is socially conditioned; it hinges on and affects the system of social relations involved in the production and exchange of goods and services (*see* ECONOMIC ANTHROPOLOGY).

In primitive society economic relations are more personalized than in industrial society; categories of employer, employed, wage earner, capitalist often do not apply. Economic services are contributed not simply to earn a living but as part of a wider system of social obligations (*see* LABOUR, PRIMITIVE).

In almost all nonindustrial societies the main economic unit is the family or household rather than the individual. All able-bodied members share, under the direction of the head of the household,

such routine tasks as getting and preparing food according to recognized patterns of division or work by age and sex. Some tasks require a wider basis of cooperation than the household: a rice-transplanting team, a canoe crew, or a hunting band. Coordination of work may then depend on the rights and duties of kinship, on central community authority, or on ritual and magic. Malinowski showed this in his analysis of the importance of the gardening magician and his rites in Trobriand village agriculture. When large working parties are assembled, their beneficiary will offer food or perhaps (as in Africa) beer. He may also make gifts, but these do not usually reflect any precise measure of the service rendered. Later, he will return the service by working for others. Technological specialists generally receive additional payment that is apt to be traditionally fixed.

Property in any society is represented by sets of rights that entitle the owners to the services of other people. In primitive society these rights vary from unconditional ownership of material objects to highly complex relationships involving shared land, ritual apparatus, or magic. The most important resource to any primitive society is land, and problems of land tenure are often complex to a Western observer (*see* LAND TENURE, PRIMITIVE). Other kinds of property are generally owned in a way more familiar to Westerners; food may be personal or household property. The house itself will belong to the head of the household, subject to the rights of other members. Tools and implements are usually personally owned. Social titles, songs, dances, magical spells, and medicines may be personal or group property; many can be sold or exchanged.

Although most essential skills are possessed by typical adults in primitive societies, goods will constantly change hands and services are continually rendered to other people (*see* GIFT EXCHANGE; TRADE, PRIMITIVE; CURRENCY, PRIMITIVE). The principle of reciprocity, or basic compensation, was strongly emphasized in the theories of Mauss, Malinowski, Firth, Thurnwald, and M. J. Herskovits; the significance of exchange of women by transfer on marriage has been demonstrated by Lévi-Strauss. A prestation (a due, paid in goods or services) is normally part of an already established relationship between two people. If the parties are of roughly equal status, a return of equal value will be made, directly or indirectly. A voluntary prestation unreturned indicates that the giver is of higher status than the receiver; the basic compensation in this case is prestige.

A primitive economic system is usually related closely to the associated political and ritual system. Productivity is believed to depend on gods and ancestral spirits, and elaborate rites are designed to secure their aid or benevolence. The system of allocating land and of distributing produce is a basic way in which chiefs and other leaders maintain status and power.

Political Relations.—Political relations concern the orderly conduct of affairs of public interest within and between communities or societies. Although they essentially involve control of people's behaviour, not even in the simplest political community are political relations based simply on force.

Many primitive societies have neither legislative or judicial machinery nor group leadership above the level of the village or camp. Yet internal and external affairs are usually conducted in an orderly fashion, and anthropologists such as Lowie have extended the use of the word "politics" beyond the field of instituted government. But primitive political systems are still tentatively classified because of their great variety. In Africa alone they range from autonomous Thonga (*q.v.*) villages, based on kinship, to large kingdoms such as Nupe and Ganda (*qq.v.*).

Fortes and Evans-Pritchard distinguished three major types of African political system: (1) small stateless societies based on kinship (*e.g.*, Bushmen); (2) larger stateless societies based on segmentary lineage systems, with uncentralized authority but with some politically significant roles (*e.g.*, Nuer); and (3) unitary states with specialized, central political authority (*e.g.*, Bemba). I. Schapera later showed that territorial as well as kinship ties are politically significant in type (1); Middleton and D. Tait noted that there are in Africa many morphologically intermediate types other than these three. In political systems of the village type there are no corporate lineages, but in central Africa, for instance, kinship and neighbourhood provide the necessary institutions for the organization of power and authority under chiefs and headmen.

Where much larger political groups exist without formal government, use is normally made of the unilineal principle of organization. Among the Nuer territorial divisions are named after the branches of the lineage system, although they do not exactly correspond to them. There is no specific authority over lineage segments. In cases of dispute no one official can order a group to accept compensation and make peace. But an elder with special powers, called by Evans-Pritchard the leopard-skin chief, usually can persuade them. Thus among this independent and quarrelsome people, group relations are ordered according to well-established moral principles.

In many parts of the world chiefs are the heads of governments. Among the Bemba (investigated by Richards) the paramount chief rules over a considerable territory. He has advisers, councilors, ritual officers, plus a whole range of courtiers and messengers, and resides in a capital considerably larger than a normal village. Members of the royal clan rule as lesser chiefs over sections of his territory, with capitals and courts similar to his. Beneath these are headmen, responsible to the chiefs. In this case, a great number of people, larger than could ever form a single kin unit, are united in one political society. The size of such a state depends primarily on the strength and efficiency of its administration, though loyalty to symbolic ties of group unity may also be important.

Relations between autonomous political groups in primitive conditions vary with size and organization of group and with ecological conditions. The normal attitude to other autonomous groups is often hostile, as in parts of inland New Guinea. Within a given political system, internal unity rests partly on opposition to external groups.

Wars between primitive communities vary greatly in aim and in ferocity, and are conducted according to specific rules. In conflicts between neighbouring groups who are kin to one another, as among the Andaman islanders, killing may be rare. Women and land, as the Maori used to say, are probably the commonest issues. Habitual raiding for cattle and slaves (once common in many parts of Africa) was without any notion of conquest. Wars of conquest are not feasible unless the conquerors have a state organization to control their subjects. Great conquerors like Shaka (or Chaka), the powerful Zulu king of the 19th century, are rare in primitive society.

Primitive military leadership and organization are often *ad hoc* and informal, though sometimes the war leader also may be the chief. Many societies have or had special war leaders with no other political tasks, as among American Indians. In eastern and southern Africa warrior regiments often existed, based on an age-grade organization. It was by reorganizing age regiments and maintaining them in royal barracks that Shaka was able to gain power and military success.

Authority in any nonliterate society must depend on the people's personal contact with the ruler or his agents. A great deal of ceremonial behaviour and story telling serves the end of transmitting norms and of ensuring that they are remembered. The society looks to the past for validation of rules and values, and explicit legislation is very rare. On the other hand, verbal transmission leaves room for continual adjustments of which the society may not be clearly aware.

Informal arbitration is found in all societies, but in many no sanction of force supports a decision, though public opinion may be a strong influence. In some American Indian societies (as Lowie showed) the function of arbitrator could be exercised only by a man who was not a war leader. In more complex societies, a political hierarchy coincides with a hierarchy of courts, with right of appeal to the paramount ruler. In Africa many societies have a constituted court and litigation is common.

At all levels of society, even where (as in Polynesia) the chief is treated with great deference, the political system provides for checks and balances. Sometimes there is provision for an assembly

of all the people, as among the Southern Bantu. Sometimes the chief, as among the Tikopia, must pass orders through subordinates who, if supported by public opinion, can tactfully evade them. Sometimes, as among the Bemba, the chief depends on the co-operation of ritual functionaries who can refuse their help. Only when a ruler can monopolize force is he able to set up a tyranny; tyranny requires a fairly complex political and military organization. Ritual sanctions behind a ruler may be strong, but they also impose on him strict rules of conduct that limit his power.

To act cohesively, people must think of themselves as a unit, and are able to do so through symbols of unity. The more powerful the emotional value of the symbol, the greater the loyalty to the group. A common and effective symbol of unity is the chief who also signifies the society's well-being and fertility. The chief is thus sacred and acquires important ritual functions. In extreme cases he may be thought of as an incarnation of a divine being. Sometimes, as among the Shilluk (*q.v.*), his own personal vigour is associated with the welfare of the society; it has been alleged that in former times when he was ailing or old he was put to death. Alternatively, the religious head of the society and the ruler may be distinct but interdependent persons.

Religious rites may also be of great importance in political relations. Among the Tallensi there were no chiefs with secular authority. Instead, ritual leaders annually conducted a great festival of autonomous clans, required during this period to settle all quarrels and refrain from hostile acts. In most primitive societies, political organization is linked with ritual and symbolism.

Ritual Relations.—Rites are formal acts not technically related to immediate purposes, but believed to have intrinsic validity. They are often symbolic in character and are usually closely related to myths and dogmas, which explain and help to validate their symbolism. Ritual behaviour ranges from the worship of God to the concocting of medicines against witchcraft or incantations to render a spear more deadly. Many authors have sought to apply the distinction current in Western society between religion and magic. J. G. Frazer suggested that religion is characterized by prayer to a personal power, magic by command to an impersonal force. Durkheim identified religion with public and obligatory rites, magic with private and optional rites. Malinowski held that magic is for immediate practical ends, religion being concerned with general well-being. But each of these criteria classifies as magic some rites that are normally called religious, and vice versa. Moreover (as Lowie, P. Radin, G. Reichard, R. Piddington, and others showed), there are too many borderline cases between prayer and command, between obligatory and optional, between practical and general purposes for these to be final criteria. The general meanings of "religion" and "magic," therefore, remain vague, though more precise classification is possible for particular societies.

All known societies include members with beliefs in a spirit world. In most primitive groups, gods and spirits are thought of as belonging to the particular society, and symbolize its unity. Dead ancestors often are important among the spirits, and belief in their powers thus reinforces lineage or other kinship systems. Myths about the spirit world are thought to explain the universe, give an account of man's place in nature, and validate moral law. They often provide a charter for existing rights and obligations between kinship groups or local groups, in such matters as ownership of lands, social status, or ritual cooperation.

Public rites may be performed simply as worship, or they may have explicit, specific aims such as the fertility and health of group members, abundance of crops, or control of the weather. The passage of an individual from one status to another—birth, initiation, marriage, death—is marked by rituals which (as the classic work of A. van Gennep and later anthropologists such as Richards showed) have important functions in social integration. Rites may also symbolize social distance, unite potential enemies, and enforce the cessation of feuds or wars. Rites such as sacrifice may expiate sins (*see* PASSAGE RITES).

Ritual and belief clearly provide individuals with important means of adjusting to their environment. Religious dogma and mythology should not be assumed to be inflexible. Skepticism, reflection, unconscious modifications in transmission, and even trial and error with ritual procedure are reported from many societies. But the system of belief provides a limiting framework within which speculation is necessarily confined. (*See* MAGIC, PRIMITIVE; RITES AND CEREMONIES; TABU.)

Social Control.—Social order consists in conformity of individual members of a society to a set of rules of conduct. People obey such rules because they wish to do so, or are conditioned to do so without conscious choice; or they are given positive or negative inducements. Social control, therefore, involves both the training of members of society and a system of rewards and punishments (sanctions) that operate to produce conformity in behaviour.

Formal education is rare outside civilized, literate societies. Children in most primitive societies learn by imitation and by participation in activity, guided by correction and praise. Initiation rites may emphasize moral rules through symbolism and explicit instruction. The solemnity of the occasion may be heightened by ordeals, including painful circumcision or scarification.

In a primitive society, formal sanctions may be carried out by community officers according to recognized procedures. But more often they are informal: unplanned individual reactions, or such group-inflicted penalties as songs of ridicule or systematic ostracism. In a small community such informal sanctions can be very strong; failure to conform, apart from material consequences, means loss of esteem and status. Even formal sanctions need not involve judicial procedure; a chief, secret society, professional body, or religious leader may act without formal weighing of evidence or statement of law.

Conduct is often controlled by the expectation that it will produce undesirable consequences apart from any human agency; *i.e.*, such an action is tabu. But belief in dire consequences may deter less than does symbolic expression of strong social disapproval. More generally, divine punishment is often said to follow moral or ritual lapses (sins); these may also be directly punished by society, especially if they are believed to endanger community well-being. But in particular sin may require confession, as R. F. Fortune showed for the Manus of the Admiralty Islands, or a sacrifice in atonement, as Evans-Pritchard and Middleton have illustrated for East African groups. The moral rules of any community are usually supported by its cosmology and by its religious myths and dogmas.

Social control is thus seen to be imbedded in the social system, a by-product of kinship, economic, political, and ritual relations. It is only in the field of law as such that social control has its own institutions.

Thurnwald and Radcliffe-Brown suggested limiting the word "law" to societies where some kind of court exists, with control of organized force to back up its decisions. By this definition many societies have no law at all. Malinowski proposed to consider as law the total body of binding custom of a society, and Lowie, K. N. Llewellyn, and E. A. Hoebel defined law in terms of action by a person against breach of a norm with communal approval or sanction. But (as Schapera showed) if such a broad definition of law be adopted to include all binding custom, there is still need to consider separately formal judicial procedures.

Primitive law involves public action to punish what are regarded as threats to society, corresponding to modern criminal law, and the settlement of private disputes, corresponding to modern civil law. The first is rare and is often confined to serious ritual offenses, especially incest, and witchcraft or sorcery. On the other hand, private disputes cover much that in Western society is criminal behaviour; *e.g.*, homicide and theft.

Specific legislation in primitive society is rare though Schapera has noted modern development of legislation by chiefs among the Tswana (*q.v.*). Where courts are found, the conduct of cases differs greatly from that in Western society. Although most cases are in the form of private disputes, the court will not hesitate to lecture both sides on their moral responsibilities—the law coincides closely with the ethical notions and public opinion of the society (M. Gluckman and P. Bohannan). Oaths and ordeals are used to establish evidence, and hearsay evidence is admissible;

professional pleaders are unusual. In punishment, fining is common but imprisonment rare; banishment or exile from the society is often the more severe penalty. (*See* LAW, PRIMITIVE.)

Values.—Social anthropologists have always paid some attention to values, usually under the head of beliefs, ideas, or institutions. Radcliffe-Brown, for example, described the social value of such phenomena as fire to the Andamanese. Later, C. Kluckhohn and co-workers made comparative studies of values among several neighbouring societies in New Mexico. R. Redfield fostered the concept of world view: the characteristic outlook of a people, and the categories they use to classify and judge all phenomena (including human actions). In a broad sense values may be described as preference qualities assigned to objects and actions in social contexts, having regard to relationships between means and ends. More narrowly, following Kluckhohn, they may be defined as conceptions of the desirable that influence selection from available modes, means, and ends of action. Some values are explicit: they can be formulated in words. Others are implicit, tacit premises implied in action. Thus the Navaho have the concept of harmony among the parts of the universe—an implicit value expressed in much behaviour but only rarely in words and expressed by singers, who are the Navaho intellectuals. Studies of individual conformity to predominant values, the relation between explicit and implicit values, and the processes of value change have received much attention from anthropologists. A problem of theoretical and practical interest (which Redfield and Nadel in particular discussed) is the degree to which anthropologists are influenced in their observations and interpretations by their own personal values.

Studies in Literate Societies.—Intensive field research and systematic analysis of social relations have not been limited to primitive or preliterate societies. Earlier anthropologists saw themselves as historians of human institutions, and made free use of materials from ancient civilizations, especially Greece and Rome. Later workers found primitive societies in transition under the rapid spread of literacy and western influences in Africa, Oceania, and other parts of the formerly primitive world.

Studies among rural communities of the folk-culture type were pioneered by Redfield in Middle America, H. M. Miner in French Canada, C. M. Arensberg in Ireland, J. F. Embree in Japan, H. Fei and F. L. K. Hsu in China, and A. Aiyappan in south India. More recent investigations of peasant communities have also been made in Europe and the Middle East. In urban communities problems of isolating the field of study have been more acute, and approach to conventional sociological methods has been closer. In recent years urban studies by anthropologists have been carried out, particularly in India and in Africa; attention has also been paid to Western industrial problems, and social and cultural factors in technical change. Social anthropologists have also developed interest in special fields such as child training and care, and the social implications of kinship ties in different societies, including those of Western countries. Social aspects of medicine and nutrition as shown in attitudes to disease and to medical care have been examined. The special problems of ethnic groups such as Negroes in Western society, and of other minority groups, in situations of differentiation and discrimination, have been studied, as have the operation and social significance of certain religious sects. Social anthropologists are thus linked with other social scientists in systematic attempts to understand the structure of complex modern societies.

(R. F.)

SOCIAL CONTRACT, in political philosophy, a term applied to certain theories of political obligation. Although similar ideas can be traced back as far as the Greek Sophists, social contract theories had their greatest currency in the 17th and 18th centuries, and are associated with such names as Thomas Hobbes, John Locke, and Jean Jacques Rousseau (*qq.v.*). What distinguished these theories from other doctrines of the period was their attempt to justify political authority on grounds of individual self-interest and rational consent. The method used was to demonstrate the value and purposes of organized government by comparing the advantages of civil society with the disadvantages of the state of nature, a hypothetical condition characterized by a complete absence of governmental authority. The purpose of this comparison was to show why and under what conditions government is useful, and ought therefore to be accepted by all reasonable men as a voluntary obligation. These conclusions were then reduced to the form of a social contract, from which it was supposed that all the essential rights and duties of citizens could be logically deduced.

Although social contract theorists were agreed as to method, the conclusions they drew from it were widely different. According to Hobbes (*Leviathan*, 1651), the state of nature was one in which there were no enforceable criteria of right and wrong. Each person took for himself all that he could; man's life was "solitary, poor, nasty, brutish and short." The state of nature was therefore a state of war, which could be ended only if men agreed to give their liberty into the hands of a sovereign, who was thenceforward absolute, on the sole condition that the lives of the citizens were safeguarded by his power. Locke (the second of *Two Treatises on Civil Government*, 1690) differed from Hobbes insofar as he described the state of nature as one in which the rights of life and property were generally recognized under natural law, the inconveniences of the situation arising from insecurity in the enforcement of those rights. He therefore argued that the obligation to obey civil government under the social contract was conditional upon the protection not only of the person but also of private property. Rousseau (*Du contrat social*, 1762) held that in the state of nature man was unwarlike and even timid, and that his rational powers were too little developed to enable him to have any conception of rights and duties. Laws resulted from the combination of men who agreed for mutual protection to surrender individual freedom of action, and thereby acquired for the first time a sense of moral and civic obligation. In order to retain its essentially moral character, government must therefore rest on the consent of the governed, the *volonté générale* ("general will"). Other social contract theorists provided yet other interpretations of the common theme.

These theories are historically important for the part they played in the development of modern ideas of government, especially the idea of government by popular consent. Toward the end of the 18th century, however, with the rise of modern historicism, they became increasingly unacceptable, not so much because of their content as because of the abstractly rationalistic terms in which they were formulated. The more perceptive social contract theorists, including Hobbes, had always recognized that their concepts of the social contract and the state of nature were unhistorical, and could be justified only as hypotheses useful for the clarification of timeless political problems. David Hume, in particular, is absolutely explicit on this point. But as people grew increasingly interested in history, and tried to understand political problems in terms of the historical origins and growth of specific institutions, the earlier types of abstract analysis seemed ever less relevant. Thus the term social contract fell gradually into disuse, and ceased to play a significant part in the vocabulary of modern politics. (F. M. W.)

SOCIAL INSECTS are insects that live in colonies in which the adults perform different tasks associated with differences in structure and function—for example, the queen lays eggs and the workers tend the nest and procure food. Social organization has evolved independently in several groups of insects in two insect orders, the Hymenoptera (ants, bees, wasps) and the Isoptera (termites). It is found in varying degrees in some species of bees and wasps, but is fully expressed in all species of ants and termites. Maurice Maeterlinck in his lyrical *The Life of the Bee* (1901) attributed the unity and communal cooperation within the colony to an elusive "spirit of the hive [that] disposes pitilessly of the wealth and the happiness, the liberty and life, of all this winged people; and yet with discretion, as though governed itself by some great duty." This spirit of the hive is now known to be a complex system of communication by means of chemicals called pheromones, or social hormones, which influence behaviour and growth of individuals and appear to be the integrating factors in all insect societies.

INSECT SOCIETY: A SUPRAORGANISM

An insect society may be compared to an individual organism, the individual members of the society being comparable to organs or cells of the organism. Such a comparison does not say anything new about insect societies but it suggests interesting approaches. An individual organism is an open system with adaptation to, and interaction with, its environment; it maintains a relatively steady-state by self-regulation of internal conditions; it has a capacity for reproduction; it exhibits functional specialization of its parts; and it shows change with development. The insect society is a supraorganism—a collection of organisms exhibiting all of the organismic properties mentioned above. The protoplasmic contact between the parts, characteristic of the organism, is replaced in the insect society by behavioural and biochemical interaction. Communication through behavioural specializations and trophallaxis—mutual exchange of food, exudates, and pheromones—is characteristic of insect societies. Analogous similarities between levels, such as nonreproductive somatic cells in the organism and

nonreproductive castes in the insect society, result from natural selection of whole units favouring division of labour, integration, and improved self-regulation (homeostasis). All the detected trends of evolution in insect societies and in organismic evolution are toward improved homeostasis.

The societies of man are analogous to insect societies in such attributes as division of labour among adults of the same sex, communication, and integration of individuals into systems (social institutions, tribes, nations). Human societies also show an evolutionary trend toward increased homeostasis to provide better conditions for existence. In these senses, human societies are also supraorganisms. They differ from insect societies, however, in having a social organization based upon learned symbolic communication. There are no genes for a particular language, a particular style of architecture, or a particular type of agriculture, as there are among social insects. The evolution of insect societies is slow, whereas the evolution of cultural traits in man is rapid. Insect societies are rigidly organized and are characterized by stereotyped and automatic responses of members; human societies exhibit much greater versatility and functional adaptability.

The success of insect societies presumably results from a division of labour among different individuals of a colony. Except in very primitive societies, the individuals performing different functions differ also in structure. Thus, the egg-laying queen is quite different from a worker or (in termites) from a soldier. These various forms are called castes. The existence of castes (a condition termed social polymorphism, or polyphasy) and their evolution and determination are subjects of continuing study.

ORIGIN

Except perhaps for some groups of bees, true social insects arose from insects that live in family groups consisting of a mother and her offspring but in which the mother dies or leaves the group after the eggs hatch and before the offspring reach maturity. Such a way of life, called subsocial, is in contrast to that of the majority of insects, in which the mother lays her eggs and leaves them immediately or dies before they hatch. In subsocial forms, the young may be both protected and fed by the mother or sometimes by both parents.

The social wasps arose from solitary wasps of the subfamily Eumeninae, family Vespidae. Solitary Eumeninae construct a cell, provision it with food, *e.g.*, paralyzed caterpillars, lay an egg in the cell, and seal it. The food is adequate to provide for the entire growth of the single larval wasp; such a cell is said to be mass provisioned. There is no contact between the larva and its mother, although the mother provided a protecting cell and all of the larval food. Wasps more immediately ancestral to social forms show various degrees of continual, or progressive, provisioning of cells; cells are left open during larval growth, and food is added as the larvae require it. Such wasps are strictly subsocial, since there is direct contact between mother and growing offspring. True social wasps all provision cells progressively.

Social bees arose, not once but repeatedly, from solitary forms nearly all of which use mass provisioning. Since most social bees also have mass provisioning, it is obvious that progressive feeding is not a prerequisite for establishment of social behaviour. Ants are related to solitary vespoid wasps, but there is no living family from which they might have evolved. Some bethylid wasps, which belong to the general group from which ants also possibly arose, have subsocial behaviour in which larvae are attended to by their mothers. These larvae are external parasites on very much larger host insects paralyzed by the repeated stings of the adult female bethylid. The larvae are therefore not in individual cells; larvae of ants also are not in separate cells but are reared grouped together in masses.

Termites arose from roaches. Subsocial behaviour of the sort that possibly was found among the ancestors of termites exists today in wood-eating roaches (*Cryptocercus*) that live in small family groups and harbour wood-digesting flagellate protozoa similar to those that serve the same function in primitive termites.

Subsocial family groups are known in a number of insect orders, but except for termites, true societies occur only in Hymenoptera. Perhaps the most important single feature increasing the potentiality for social development in Hymenoptera is the possession of sensory and central nervous equipment good enough to permit the insect to find food and then successfully return, repeatedly, to its nest. Solitary bees and wasps, which have such abilities well developed, constitute a great pool of organisms from which social forms could evolve repeatedly.

SOCIAL WASPS

The social wasps include more than one thousand species of the family Vespidae. Some of the larger and more aggressive species, called yellow jackets and hornets, are respected for their very effective stings. Although adult social wasps are attracted to flowers, decaying fruits, and the like for their own sustenance, they collect animal food (largely chewed up insects) to feed their larvae, along with liquids from the same sources as part of the adult food. One genus of the New World tropics (*Brachygastra*), however, stores honey in papery cells. Social wasps construct paperlike nests composed of chewed dry plant material, usually wood, mixed with saliva. These nests usually consist of one or more layers of cells covered with a papery envelope. The cells, hexagonal in cross section, are usually vertically arranged with the openings downward. Depending on the kind of wasp, the nests may be found in cavities in the soil, in tree trunks, or hanging from leaves, branches, or eaves of buildings. Eggs, larvae, or pupae are found in the cells, one per cell. Eggs and small larvae are held in the cells by an adhesive material; the older stages retain their position by means of their snug fit. The mature larva spins a cocoon, lining and capping the cell, before it pupates.

When they are fed, larvae emit from their mouths secretions that are much in demand by the adult wasps. This exchange of substances—the larva receiving food brought to it by the adult and the adult receiving the secretion of the larva—and other sorts of mutual stimulation are termed trophallaxis. It is very widespread among social insects and is among the integrative mechanisms that make the colony a successful operating unit.

Workers rarely or never develop into egg layers. In the large subfamily Polybiinae, especially common in the American tropics, the colonies often contain many queens, as well as even larger numbers of workers. In this group queens and workers are scarcely distinguishable externally, although in ovarian development, physiology, and behaviour they are quite different. New colonies are founded by the swarming of several queens with many workers, a type of colony establishment not found in other social wasps.

The most familiar social wasps in the temperate zones are species of *Polistes* (subfamily Polistinae) and of the genera *Vespa, Vespula,* and *Dolichovespula* (subfamily Vespinae). These wasps and hornets have colonies that last a single season. There is ordinarily only a single queen in a colony except in autumn when new young queens and males are produced. In autumn the wasps perish except for the recently mated females, each of which may establish a new colony in spring.

The *Polistes* queen builds a few cells attached to a single stalk hanging downward in a sheltered place, often under the eaves of a house or shed. Her first progeny consists entirely of females (workers). After their appearance, the queen no longer leaves the nest, for food is brought to her by the workers. Workers add new cells laterally to the enlarging comb, which ultimately may attain a size of 500 cells or more. The comb of *Polistes* is naked, without a paper envelope. Nests of the other genera listed above are established in a similar manner, although those of *Vespula* are usually in underground cavities. The combs are surrounded in these genera by an envelope consisting of several layers of paper with a hole at one point through which wasps can come and go. As the colony grows, additional combs are constructed in tiers beneath the original comb. The paper envelope must be enlarged as new combs are added; this is done by removing inner layers of the envelope and adding new layers on the outside. Nests of Vespinae may become very large, up to two feet in diameter in the temperate zones and even larger in tropical Asia. Both the queen and the workers are equipped with stings with which they can defend themselves and the colony.

Socially parasitic wasps that have lost the worker caste have evolved in both Polistinae and Vespinae.

SOCIAL BEES

The bees (superfamily Apoidea) are wasplike insects that differ from wasps primarily in that they feed their larvae on pollen and honey instead of on insects or other food of animal origin. Of the probably 20,000 species of bees, 1,000 or more are primitively social and probably less than 500 are as highly social as bumblebees and honeybees.

Primitively social bees are those in which workers and queens are scarcely, or not at all, distinguishable externally (although usually they differ in average size). Of course there are striking behavioural and physiological differences between castes. The most familiar primitively social bees are among the sweat bees (Halictidae). All intergradations from solitary to social exist in this family. The nests consist of burrows, usually in the ground, leading to cells. Each cell is a cavity, lined with waxlike material, in which sufficient food (pollen mixed with nectar) is stored to provide for the growth of a larva. After an egg is laid on top of the food mass, the cell is sealed. In many species the female dies before emergence of her progeny, but in some species several females, probably sisters, live together and make cells in a single nest. In such cases the rare unfertilized female may be relatively short lived but do a great deal of work during her life, thus being workerlike. In certain species about half of the females in the colony are workerlike in this sense. Finally, in a large number of species, there exist behaviourally distinct castes that usually differ in average size. Colonies consisting of a queen and two or three workers are common, although there are species that have colonies of up to a few hundred individuals. In temperate climates the colonies are started each spring by overwintered, fertilized queens working alone, as in temperate zone social wasps. The first offspring produced are mostly workers, which enlarge the nests and take over foraging activities. In some species new queens and males are produced throughout the summer so that queens are replaced from time to time; in other species overwintered queens survive through the summer, and new queens and males appear only in late summer.

Another group of primitively social bees consists of genera related to *Allodape*, all found in the tropics or southern continents of the Old World. They nest in burrows in stems or wood, the larvae being reared together in the burrow and fed progressively. Queen and worker castes, differing from one another about as much as those of halictids, have been recognized in one Australian genus, *Exoneura*.

Bumblebees (genus *Bombus*) are the most primitive of the thoroughly social bees. About 300 species are found in the north temperate and Arctic regions, and a few extend into the tropics. As with temperate social wasps and halictid bees, the fertilized female, or queen, overwinters, usually in the ground, and seeks a nest site in the spring. Most species use empty mouse nests or animal burrows in the soil, but a few construct nests elsewhere from feathers or grass stems. After the nest site is selected, the queen gathers pollen and nectar, mixes them into a paste, and builds a circular wall of wax around the lump of paste on the floor of the nest cavity. Wax is produced from both dorsal and ventral abdominal glands. She lays several eggs in a clump on the lump of paste and closes over the wax cell. Soon after the first batch of eggs is laid, the queen builds a large wax honeypot at the entrance of the nest and in this stores honey for her own use. The eggs hatch in a few days, and the larvae soon devour the paste, after which they are fed progressively by the queen, who forages for food. The wax cell is enlarged as the larvae grow; after ten days or so the larvae spin separate cocoons of silk for pupation. The resulting adults are all workers, usually less than half the size of the queen. They relieve her of foraging activities, enlarge the nest, build new cells, and store more honey and pollen in newly constructed pots of wax. For a considerable period of time, only worker progeny are produced, and the colony grows until it contains 50 to 600 bees. In late summer, with the large population of workers bringing in abundant food, males and new queens are produced. After the queens are fertilized, all individuals except the mated young queens die. Even in the tropics, bumblebee colonies are short lived and are established by lone queens just as in the temperate zone, not by swarms as with the bees discussed below.

Socially parasitic bumblebees of the genus *Psithyrus* evolved from *Bombus*; *Psithyrus* lacks the worker caste and pollen-collecting apparatus.

Several hundred species of tropical bees without stings are called the stingless honeybees. There are two principal genera, *Melipona* and *Trigona*. Although stingless, these bees are often well able to defend their large colonies for they swarm over the intruder, often biting with their jaws and, in one subgenus of *Trigona*, working a highly irritating substance into the skin with their jaws. The queens are specialized in that they have lost the pollen-gathering and pollen-carrying apparatus and therefore are unable to establish colonies by themselves but must have help from workers. Each colony ordinarily contains only a single queen. In *Melipona*, queens come from cells mixed with, and indistinguishable from, those producing workers; moreover, queens are produced in large numbers, and all but a few are killed off by workers. In *Trigona*, as in the true honeybee, queen cells are much larger than the others, and only a few queens are produced each year. Nests are found in hollow trees, more rarely in cavities in the soil or in walls of houses and the like. A few species make their nests only in cavities in nests of ants or termites. Nest construction is with a mixture of wax and resin. Brood cells are usually in horizontal combs, the cells opening upward, but they may be in irregular clusters.

Pollen and honey are stored in pots, quite different from brood cells, and varying in size among different species, from the size of a pea to an inch or more in diameter. The adult bee population varies, among species, from a few hundred to more than 50,000. After each brood cell is provisioned, the queen lays an egg in it and then it is closed by a worker; mass provisioning is practised even in these highly social bees.

To establish a new colony, workers locate a suitable site within their flight range and carry construction materials to it from the mother nest, build part of the new nest, and even take honey and pollen to it. After a few weeks, a considerable number of workers are living there, and ultimately a newly emerged queen also flies there to become queen of the new colony. Food may still be provided from the parent colony for several additional weeks. Colonies of the stingless honeybees are perennial.

There are no true social parasites among the stingless honeybees, but the genus *Lestrimelitta*, derived from *Trigona*, consist of robbers. Workers of *Lestrimelitta* do not visit flowers but steal food from colonies of *Trigona* and carry it back to the *Lestrimelitta* colony.

True honeybees constitute the genus *Apis*, which contains the common domestic honeybee and a few other species found in the tropical Orient. The common honeybee (*Apis mellifera*) is a native of Europe, western Asia, and Africa; it has been widely introduced throughout the rest of the world. The natural location for its nests is hollow trees, although cavities in cliffs and even the ground are sometimes used. Man-made hives merely take advantage of behaviour patterns of the insect, which have probably not been changed by domestication. These bees construct hanging vertical combs of wax (for details *see* BEE and BEEKEEPING). Feeding of larvae is progressive, the cells being left open until the larvae are nearly ready to pupate. Much of the activity of the young bees in the nest consists of feeding the larvae; there may be many thousands of larvae in the colony at one time, and in the last day of larval life, for example, each receives about 2,000 feedings.

As with stingless honeybees, the queen is unable to forage alone, and colony establishment is by means of swarms. Shortly before the appearance of adult new queens in early summer, the old queen and thousands of workers leave the nest in a swarm. They fly to a tree or other support where they settle while scouts locate suitable nesting sites; in due course the swarm flies to such a site and establishes itself there.

ANTS

The ants (family Formicidae) constitute the largest group of social insects. Varying degrees from relatively simple to highly specialized social behaviour exist among the more than 5,000 species. Nearly 600 species and subspecies occur in the United States. Many of them excavate galleries in the soil or in fallen logs, but many species are mound builders on the surface of the ground, or are arboreal, living in natural or prepared cavities of plants or constructed nests. The nests are always loosely organized and lack the cells and similar precise construction of those of bees and wasps. Eggs are gathered by the workers in masses, and larvae are carried to favourable temperature and moisture conditions in the nests and may be sorted by stage of development by worker nurses.

Ant workers, unlike those of bees and wasps, are always wingless. In primitive ants (for example, most Ponerinae) workers are of one size (monomorphic) and structurally similar to the queen, although lacking simple eyes, wings, and well-developed ovaries. (Occasionally workers may lay eggs, however.) More specialized ants in most subfamilies have workers of differing sizes (polymorphic), and in many genera nutritive and protective functions may be somewhat divided among different-sized workers. Commonly the largest workers have relatively larger heads and jaws and are called soldiers. Soldier ants are not a clearly distinct caste like soldier termites (*see* below); they are merely the largest of the ant workers. Large workers may be behaviourally specialized for protection in that they are aggressive and attack disturbing objects. In some genera, however, the large-headed individuals are nonaggressive and apparently serve an important function in crushing seeds, which would not otherwise be available for food.

FIG. 1.—ANT (PRENOLEPIS IMPARIS)

(A) An ordinary worker; (B) a worker greatly distended with syrup for transport to nest

Most male and queen ants are winged. They are produced at certain seasons; in most species their emergence from parental nests is synchronized among numerous colonies so that crossbreeding is possible. Males mate with females during the mating flight or on the ground after the flight. After mating, the queen breaks, or chews off, her wings and seeks a place to establish her nest. The site depends on her species, but in the commonest temperate zone forms it is a small chamber excavated in the ground. The queen's large thoracic wing muscles, no longer useful after the flight, are absorbed and presumably assist in nourishing the queen and her first larvae, which she feeds progressively by salivary secretions. The new queen takes no food except her own eggs; she does not leave her closed chamber. This behaviour is called cloistral colony establishment. In the primitive subfamilies Myrmiciinae and Ponerinae, cloistral nest establishment does not occur; the queen leaves her nest chamber at intervals to seek food. As soon as her first young, all of which are workers, are produced, they undertake foraging. The colony may grow to contain many thousands of workers before any reproductives appear.

In a few groups like the army ants (Dorylinae), the queen is wingless, and new colonies are formed by division of the old colony rather than by nuptial flights. In some ants (for example, *Formica ulkei*), new queens are accepted back into the old nests after the nuptial flight, and new colonies are formed only later, by division of the populations. Some species of *Formica* are temporary social parasites, that is, queens start their colonies by being social parasites in the nests of some other species of the same genus. They are accepted in nests of the temporary hosts and lay their eggs; ultimately the host queen is killed, and the young of the parasitic species are reared by workers of the host species; the host workers finally die of old age and are replaced by the workers of the new queen. Once this process is complete, no evidence remains of the parasitic nature of such species. A few ants are permanent social parasites, having no workers and no independent colonies but living always in colonies of the hosts.

The food of ants is much more diverse than that of social wasps or bees. Primitive ants resemble their wasp ancestors in preying upon living insects. A few specialize, but most are general predators. The army and driver ants are important raiders, mainly on insects of the earth surface. Most of these primitive predatory ants possess the sting of their wasp ancestors. Many more specialized ants are scavengers, feeding alike on dead or living insects and larger animals, decaying fruit, etc. Some ants supplement their diet with the sweet excreta of aphids; shelters are sometimes constructed for these "ant cows."

"Honey ants," like those of the genus *Myrmecocystus*, exhibit a remarkable specialization for conserving sweet liquids. Honeydew, or nectar, is stored in the crops of some workers until they become so distended with sweet liquid that they become immobilized. Such workers, called repletes, can only hang from the roof of the nest and regurgitate honey as required by other workers. So far as known, repletes are morphologically identical to other workers in the colony. If the repletes are removed from a colony, other individuals soon become distended to replace them.

Harvesting ants collect, husk, and store seeds in cavities in their nests. The fungus-growing ants feed only on special fungi, different for each species of ant. They cultivate the fungi in chambers of their nests, usually underground. The primitive fungus ants use a substratum of insect droppings as a culture medium, the more specialized species cut pieces of leaves and petals and transport them to their underground chambers, where they are chewed into a moist spongelike mulch on which the fungus grows. In these ants there is much worker polymorphism. The largest workers function as soldiers, the middle-sized workers do most of the harvesting of leaf fragments, and the smallest workers, which never leave the nests, tend the fungus gardens. Before her nuptial flight, the queen fungus ant takes a pellet of fungus into a pouch below her mouth. After mating and establishing herself in a chamber in the soil, she places the pellet on the floor of the chamber manuring the fungus with her droppings. Her eggs are laid in the developing fungus garden, and the larvae are fed on fungus or on some of her other eggs. The first small workers appear in about 40 days and soon start foraging for leaves to enlarge the fungus garden. When larger workers appear, the smallest no longer leave the nest. The larger species of fungus ants (*Atta*) make some of the largest nests, consisting of many chambers up to 18 in. in diameter down to depths of 16 or 20 ft. and with over a thousand openings spread over a wide area from which the ants issue to defoliate trees.

In the slave-making ants of the genus *Formica* (subgenus *Raptiformica*) the colony is founded by a queen invading, as a temporary social parasite, a nest of the slave species (another *Formica*) and adopting some of the larvae and pupae. The workers that later emerge from such adopted brood feed and attend the slave-making queen and care for her brood like that of their own species. The queen of the slave species ultimately is killed or dies. The progeny of the slave-making queen emerge as workers and raid slave species in the vicinity to replenish the dwindling population of slaves. These raids may have evolved from predatory hunting by ancestral species. The loosely organized group of slave makers finds a nest of the slave species, invades it, and captures grown larvae and pupae in addition to an occasional young adult worker. These are carried off to the home nest and when mature perform the foraging, feeding, and nest-building activities of the colony. Such slave makers are also capable of living and performing their own work without slaves. The proportion of slaves varies among species and also among colonies of the same species.

Amazon ants of the genus *Polyergus* are obligatory slave makers. New colonies are established as with *Raptiformica*. The slave raids are made by workers of *Polyergus* that seem to have no other function. One or two hundred slave makers emerge from their nests and travel in an excited manner directly to the nest of a neighbouring *Formica*. There the slave makers crowd around the opening of the nest and enter as rapidly as possible. Any *Formica*

worker offering resistance is immediately killed by the sickle-shaped mandibles of the Amazons. After 10 or 15 minutes a line of Amazons returns to their nest carrying their captives. These ultimately develop into mature slaves and function in the colony as if it were their own. In artificial nests one slave can keep ten Amazons well fed, but without slaves the slave makers starve even in the presence of abundant food. Slave making among ants appears possible because adults emerging from enslaved pupae exhibit at least some of the distinctive behaviour patterns of the host species. Artificially, for example, adults of a normally timid species reared in a colony of an aggressive species are more aggressive than is usual for their kind.

Ants may become highly adapted to certain plants with natural cavities in their leaf petioles, thorns, twigs, trunks, or roots. In some cases evolutionary adaptation may be largely in the ants rather than in the plants. For example, ants of the genus *Oecophylla*, in tropical Africa and the Orient, construct their arboreal nests of leaves attached to one another by means of silk spun from the salivary glands of the ant larvae. Some workers hold the leaf edges together, while others, holding larvae in their jaws, weave the silk-secreting larvae back and forth from one leaf to the other, thus fastening leaves to form a protective nest. On the other hand, some plants appear to have evolved along with the ants associated with them. For example, the hollow thorns of the bull-thorn *Acacia* are always inhabited by ants of the genus *Pseudomyrmex*, some species of which do not occur except on these plants. These species feed only on the nectar secreted by glands on the leaves of the tree and by proteinaceous Beltian bodies produced by the young leaves. The tree thus provides protection and food for the ants, and the aggressive ants effectively protect the *Acacia* from leaf-feeding insects and browsing animals; moreover, the ants bite off vines and other plants that grow into the foliage of the *Acacia*. The association is so firm that the survival of this species of *Acacia* is thought to be dependent on the presence of these ants. Many similar cases of interdependence of ants and ant plants exist, especially in the tropics.

Inquiline insects or "guests" occur in the nests of many social insects. Numerous groups of insects and a few other animals are predators or scavengers in ant nests, but the more specialized myrmecophiles have trophallactic relations with the ants, often producing secretions that attract the host ants. Tufts of hairs, called trichomes, that disperse liquids and scents from glands at their bases have evolved convergently in myrmecophiles, for example, in several different families of beetles.

TERMITES

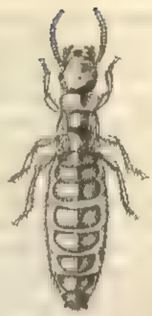
Termites, sometimes misleadingly called "white ants," show a remarkable social convergence to ants though, as mentioned earlier, they were derived from roaches. They develop by incomplete metamorphosis through nymphal stages instead of by complete metamorphosis through larvae and pupae, as in Hymenoptera. The primitive *Mastotermes* of Australia, unlike other termites, has a large lobe on the hind wing and lays eggs in groups, in both respects resembling roaches. Termites feed principally on dead plant material: wood, dead grass, dead leaves, dry droppings of grazing animals, etc. One group in the Old World tropics cultivates and eats fungi, as do the fungus ants of the American tropics. Termites of the north temperate zone are mostly wood feeders.

There are over 2,000 known species of termites, mostly tropical. The social organization differs from that of Hymenoptera in that each caste consists of both sexes. Instead of having males and females, with the latter segregated into queens and workers, as in Hymenoptera, the castes are reproductives (kings and queens), soldiers, and, in specialized termites, workers.

FROM C. L. MARLATT, "ENTOMOLOGICAL BULLETIN", U.S. DEPT. OF AGRICULTURE

FIG. 2.—RETICULITERMES FLAVIPES, FULLY WINGED MALE

The winged primary reproductives make a dispersal flight, usually synchronized among the colonies of a neighbourhood and occurring at a time of high atmospheric humidity. They leave the parent colony, fly through the air, and descend to the ground. Then they break off their wings along breakage sutures near the bases. Usually it is only after this event that the male is attracted to the female by odour. Once the pair meet, they walk in tandem across the ground as she seeks a crevice or place to excavate into dead wood or into the earth. The first progeny of a pair of primary reproductives among the lower families of termites mostly remain as working nymphs for a long time, although a few soon become soldiers. The colony usually attains a population of thousands before primary reproductives are produced. Among the specialized termites, the first progeny mostly become workers, although a few, perhaps 10%, become soldiers. Again, the colony must attain a considerable size before the first primary reproductives are produced. Some termite colonies become the most populous of any social insects, having several million individuals.



FROM N. BANKS AND T. E. SNYDER, "REVISION OF THE NEARCTIC TERMITES"; SMITHSONIAN INSTITUTION

FIG. 3.—RETICULITERMES VIRGINICUS, BRACHYPTEROUS QUEEN, WITH SHORT WING PADS

Among specialized termites, the queen develops enormous ovaries, and the abdomen becomes greatly distended (up to four inches long); after several years such a queen may lay 8,000 eggs per day continuously for years. Queens of some primitive termites grow little from their size at the dispersal flight. The king lives with the queen throughout life, and mating occurs periodically. Upon the death of the primary king or queen, one or more nymphs may develop into unwinged secondary reproductives and substitute for the lost primary one.

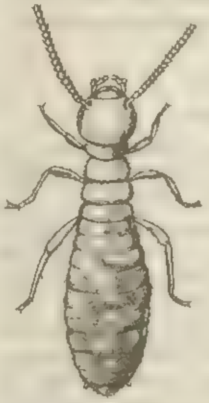


FIG. 4.—RETICULITERMES FLAVIPES WORKER

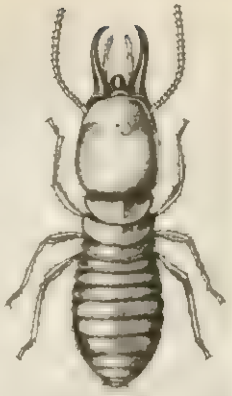
All termites possess soldiers for defense except two genera in which this caste has been secondarily lost. Soldiers have no wings, no eyes, and much reduced reproductive organs. Adult soldiers serve only for defense; being incapable of feeding themselves, they must be fed by nymphs or workers. Soldiers of most termites have enlarged heads and jaws, but some Termitidae have soldiers with reduced jaws; instead, the front of the head is prolonged into a sort of squirt gun for forcibly ejecting a sticky and irritating liquid from a large gland in the head. This defense is highly effective against marauding ants. Rarely two or three different types of soldiers occur in the same colony. An extreme case is found in two tropical American genera. Here the largest soldiers have large defensive mandibles, but the small soldiers have reduced mandibles and a large gland in the head that secretes a substance that runs down the upper lip, or labrum, and volatilizes as a repellent gas.

In termite colonies there are large numbers of immature forms, or nymphs, which do much of the work of the colony, enlarging galleries, feeding reproductives, carrying eggs away from the queen, and feeding younger nymphs that are not yet able to eat by themselves. Growth of termites is rather slow, especially among the primitive families, so that a large population of such working nymphs exists. Only in the specialized families Rhinotermitidae and Termitidae does a true worker caste exist. Workers are merely individuals whose development stops while they still have the form and behaviour of the working nymphs. Being adults, workers have lost the potentiality possessed by nymphs of continuing development and becoming soldiers or reproductives.

Most primitive termites are wood eaters, living in galleries chewed out of wood. Such termites build partitions from their excrement but do not construct nests. The more specialized Rhinotermitidae usually use wood in contact with the ground and make tunnels into the ground, for which reason many are spoken of as subterranean termites. Often the queen is in galleries in the soil, and the burrows may extend for some distance from this cen-

tral location or nest to the wood. Sometimes covered passageways extend, for example, across the surface of the foundation of a house and make available wood that is not in direct contact with the earth. The most advanced family of termites (Termitidae) contains most of the known species, nearly all of them tropical. Most of them make distinctive nests to which workers and working nymphs bring food. Some are excavated in the soil, whereas others are mounds rising up to 30 ft. high. Others make globular or oval nests of bits of wood and excrement cemented together with saliva and attached to trunks or branches of trees. The most elaborate nests are those of the subterranean genus *Apicotermes*, noteworthy for the geometrically arranged ventilation pores in the walls. The nests result from group behaviour, and symmetry, replication, homology, recapitulation, and vestigial features can be recognized in their structure, just as they are noted in the structure of the termites themselves.



FROM N. BANKS AND T. E. SNYDER, "REVISION OF THE NEARCTIC TERMITES"; SMITHSONIAN INSTITUTION

FIG. 5.—PRORHINOTERMES SIMPLEX, SOLDIER

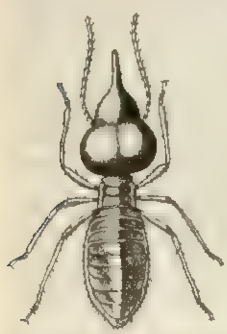
No social parasites are known among termites, although there are a few Termitidae that nest only in mounds of other species of the same family. The termites, especially the Termitidae, harbour in their colonies a host of termitophilous beetles, flies, bugs, caterpillars, etc., with remarkable exudatory organs adapted apparently to trophallactic exchange.

LIFE OF THE COLONY

Sex and Caste Determination

In nearly all Hymenoptera, unfertilized eggs develop into males and fertilized eggs become females. There are exceptions to this generalization, however: homozygous fertilized eggs in certain parasitic Hymenoptera produce males; unfertilized eggs of certain ants (*Oecophylla* species) produce females, as do eggs laid by unfertilized workers of the common honeybee occasionally and by the South African race of honeybees regularly.

In most social Hymenoptera the queen lays both fertilized and unfertilized eggs, thus producing offspring of both sexes. Eggs occasionally laid by workers, which rarely mate, are usually unfertilized. A high percentage of the males of some of the halictid bees may result from worker-laid eggs; the workers in this group have ovaries often sufficiently developed to produce eggs. In many hymenopteran colonies the loss of the queen permits ovarian development among workers so that many worker-laid eggs and ultimately many males may be produced before the colony finally dies out for lack of a queen.



FROM N. BANKS AND T. E. SNYDER, "REVISION OF THE NEARCTIC TERMITES"; SMITHSONIAN INSTITUTION

FIG. 6.—NASUTE SOLDIER OF TENUIROSTRITERMES TENUIROSTRIS

After several matings the queen honeybee has a supply of sperm adequate for her entire life; these are stored in the sperm sac, or spermatheca. She can release a few sperm onto an egg just before it is laid by relaxing a muscle that closes the spermathecal duct. Little is known about the factors that cause queens to fertilize some eggs and not others, but in the honeybee the structure of the cell in which the queen is laying is involved. If she lays in a small (worker) cell where her abdomen fits snugly, she is stimulated to release sperm cells and lay a female-producing egg. The same is true if she lays in an extraordinarily large (queen) cell. But when she lays in a cell similar to the worker cell but slightly larger so that her abdomen does not fit snugly, she is not stimulated to release sperm, and a male egg results. In a sense, therefore, the workers are ultimately responsible for determining the sex of eggs laid by the queen, since they construct the cells.

Why is it that some female eggs develop into queens and others into workers? The environment (food or other aspects) plays a most important role in determining the caste. Caste determination can occur at almost any stage in development from egg to adult and may occur at different stages among individuals of a single species. In some forms having weak caste differences, determination occurs in the adult stage. This is true in some halictid bees (*Lasioglossum marginatum*), as well as in the polistine wasp *Polistes gallicus*. In the latter, if several overwintered potential queens start a common nest in the spring, a socially dominant one becomes the queen, while the others, although mated, have the short life, small ovaries, and behavioural characteristics of workers. If the dominant individual is removed, however, one of the others replaces her as queen. In the same species, workers of the ordinary sort produced in the summer are determined in the larval stage instead of in the adult.

In the honeybee the castes are determined in the young larval stage. Larvae in queen cells are fed exclusively bee "milk" or royal jelly, a secretion of the pharyngeal glands of young adult workers, while larvae in worker cells are fed such a substance for about 2½ days, after which they receive bee "bread," a food consisting largely of honey and pollen. Female larvae can be shifted from queen to worker development or vice versa providing that transfer to the new type of cell occurs before the larva is 2½ or 3 days old. It is evidently the size and shape of the cell that stimulates nursing workers to feed the larva in a cell in a particular manner that results in one caste or the other.

In spring, queen cells are constructed in small numbers in nearly every colony. However, at other times of year they are constructed only if the queen dies or is removed. The result is production of replacement queens after the original queen is lost; such queen cells can be constructed around eggs or young larvae already present in the colony but not yet determined as to caste. Mechanisms determining construction of queen cells (other than those normally constructed in the spring) have been studied in detail. The presence of a laying queen inhibits the construction of other queen cells and also inhibits ovarian enlargement among workers. Queen cell construction and ovarian development are also inhibited in queenless colonies if workers are continuously introduced from the presence of a queen or if bodies of dead queens or extracts of queens are introduced. Mere sight, sound, or odour of queens have little effect. The inhibitory influence is "queen substance," a pheromone identified as 9-oxodec-2-enoic acid. This substance is stored in the mandibular glands of the queen and is released through the ducts of these glands opening at the bases of the mandibles. It is obvious that in a populous colony, *e.g.*, 50,000 bees, relatively few individuals can contact the queen each day; yet queen cell construction begins only a few hours after the loss of a queen. This must be a reaction to the decrease in the total concentration of queen substance among the aggregate of workers; the substance is transferred by mutual food exchange and licking among the workers and thus influences all members of the colony continuously. There is evidence that queen substance is not the only pheromone involved in inhibition of queen cell construction, but other pheromones have less noticeable effects.

Among some ants, larvae are undetermined as to caste late into the last larval stage, while in other species caste is fixed in the first larval stage, and a strong caste bias may exist even in eggs. Such environmental factors as kind and quantity of food and the developmental stage that the larva has reached when it goes into winter quiescence are involved in caste determination. In species where caste bias appears in eggs, important factors are the temperature of the queen and the kind of food that she is receiving at the time the eggs are produced.

Only in the stingless honeybee, *Melipona*, is there an indication that queen and worker eggs differ from one another genetically. Kerr (1950) has shown that under certain conditions queens are produced at the rates approaching 25% (for one species) and 12.5% (for other species) of the total female production. Most young queens are killed off by workers; they cannot be useful in such enormous numbers. These rates of queen production suggest a genetic agency.

In termites the control of social polymorphism is due to a very complicated mechanism involving several pheromones. Probably

all individuals have the initial tendency to develop as reproductives. For some reason that is not known, large numbers achieve this caste in established colonies at certain seasons when winged reproductives are produced and leave the colony. Otherwise, pheromones, different for the two sexes, secreted by the king and queen, licked from their body surfaces, and transmitted among the members of the colony by interchange of food and mutual licking, inhibit nymphs from developing toward the reproductive condition. On the death of a queen, however, her inhibitory pheromone is no longer produced, and one or more female nymphs of the appropriate age and sensitivity to the reduction in concentration of the pheromone develop as secondary queens. The great majority of nymphs are inhibited from developing as reproductives and tend to become soldiers. Soldiers also secrete inhibitory pheromones, in such quantities that, if roughly 10% of the adults in a colony are soldiers, inhibition of development toward soldierhood occurs. If the percentage of soldiers drops below 10%, then some nymphs are able to become soldiers. Nymphs that are prevented by inhibitory pheromones from becoming reproductives or soldiers probably tend to remain for long periods in the nymphal stage in the more primitive families of termites or mature as adult workers in the more specialized families. Detailed studies based on *Kalotermes* indicate that the above summary is simplified and that there are pheromones that promote as well as inhibit development toward certain castes. In a termite colony having an excess of reproductives or soldiers, the excess will be killed and eaten by workers and nymphs until the normal relative abundance of castes is reestablished (another group of pheromones stimulates the eating of excess reproductives or soldiers).

In the highest termites (some Termitidae) castes are in part genetically controlled. This is suggestive of *Melipona* among bees. In both bees and termites, evolution has seemingly been toward the taking over by genetic mechanisms of caste control that was originally environmentally regulated.

Foraging and Communication

There are obvious advantages to any social insect that forages far from its nest to have the ability to communicate to its colonymates about a food source it has found. There is no evidence of such communication in primitively social bees, in bumblebees, or in ants that make use of widely scattered small food sources like grass and weed seeds. In some other social insects, the communication related to foraging is merely social facilitation; *i.e.*, a successful forager stimulates other workers of appropriate age and physiological condition to go out foraging, but no information is conveyed as to the location of the food sources. Such stimulation occurs in certain kinds of ants (*Formica*), in social wasps, and in stingless honeybees (some *Trigona*). In many ants, however, trail-marking pheromones integrate the foraging procedure. Such ants generally exploit food sources too large to be carried back to the nest by a single ant. Probably only a small percentage of the workers, presumably the oldest and most experienced, go out from the nest as individual foragers or "scouts." On finding food, a scout takes a sample back to the nest, using her knowledge of landmarks, odours, the position of the sun, and the like, to take a more or less direct course back. On the way back she marks her trail by dragging or lowering her abdomen and releasing a pheromone. This substance stimulates other ants of the same species to follow the marked trail and come upon the food source. If the food source is rich, the trail becomes better marked and therefore increasingly used. By using the gland substance it is possible to make artificial trails that ants will follow. Chemically marked trails permit the colony to utilize relatively young and inexperienced workers that cannot find their way as lone foragers. The trail pheromones of some ants are extremely volatile so that only relatively short trails are possible and foraging occurs close to the nest. For other species, the trail pheromones are more lasting, and trails can sometimes be followed by ants after days or weeks of disuse and even after rain.

Some stingless bees (*Melipona* and some *Trigona*) use a similar device. After a forager has returned several times from a newly found food source to the nest, she alights at frequent intervals leaving odour spots (mandibular gland secretion) on the ground or on vegetation. Once back in the nest, she stimulates other potential foragers by a high-pitched buzzing sound and then leads a group of them out of the nest and along the trail of odour spots to the food. In contrast to the ants, both a leader and an odour trail are involved, possibly because the pheromonal trail cannot be continuous in the case of a flying insect.

Some termites are also capable of leaving odour trails using a gland on the underside of the abdomen.

The remarkable system of communication in honeybees was discovered by Karl von Frisch. A honeybee that has found a rich food source marks the food with an odour emitted from a scent gland on the apex of its abdomen. After returning to the hive, the bee may impart the odour of the food to other bees, but the main items of importance—distance and direction to the food—are conveyed by "dances" on the vertical combs in the hive. For northern European honeybees, if the food is 50 m. or less from the hive, the scout performs a round dance making circles first in one direction and then the other, about an inch in diameter, running on the surface of the comb. If the distance is between 50 and 100 m., the dance includes a short straight run between turns, and the abdomen is wagged from side to side during the straight run. For distances greater than 100 m., the straight run between two half circles is considerably longer. The speed of the dance, as well as sounds associated with it, varies with distance. For distances under 100 m., direction is scarcely indicated, but over 100 m., the direction of the straight wagging run indicates the direction of the food in relation to the position of the sun. If the food is toward the sun, the straight run is vertical, up the comb. A downward run indicates a direction away from the sun. A deviation of, for example, 10° to the right of the vertical indicates the direction of 10° to the right of the direction toward the sun. Any angle in the compass can be indicated by this system. Of course, the dance is modified as the sun moves. If the sun is straight up (noon during certain days in the tropics), communications stop from a few minutes before to a few minutes after noon. During a period of light overcast, bees orient by perceiving cloud-penetrating ultraviolet radiation from the sun. If any blue sky is visible, they get their cues from the polarization of light from the sky. Similar communication is used by swarming bees to transmit information about suitable nesting sites to members of the swarm. Minor heritable differences exist among communication systems of various geographical races of honeybees. Bees in colonies made by mixing subspecies misunderstand the dances of individuals of races other than their own.

Martin Lindauer examined in detail the communication by which workers learn for themselves the current necessities of the hive. They do this by extensive patrolling and inspection. Apparently their alertness to the needs of the hive makes every bee available for community work at any moment, without the necessity for a direct summons from other bees. Pheromonal stimulants to aggression occur in ants and bees. In the honeybee such a pheromone is liberated when a sting is inflicted, stimulating other bees to sting also.

SOCIALISM, a broad term that generally denotes a system of public ownership and management of the means of production and distribution of goods as contrasted to capitalism (*q.v.*), that emphasizes private ownership and management. There are many varieties of socialism and the term has had a long and a complicated history. The presentation of the subject in this article follows historical lines and is based on the following outline:

- I. Early Socialists and Their Predecessors
  - 1. Origins
  - 2. The Saint-Simon and Fourier Doctrines
  - 3. Owenism

I. EARLY SOCIALISTS AND THEIR PREDECESSORS

1. Origins.—The words socialist and socialism came into use in Great Britain and France soon after 1825, and were first applied to the doctrines of certain writers who were seeking a complete transformation of the economic and moral basis of society by the substitution of social for individual control and of social for individualistic forces in the organization of life and work. Socialist seems to have been used first in Great Britain (*Co-operative Magazine,* 1826) to describe the followers of Robert Owen, and the word *socialiste* in France (*Globe,* 1832), with reference to the followers of Claude Henri de Rouvroy, comte de Saint-Simon. In Great Britain the followers of Owen officially adopted the name Socialists in 1841. The word socialism as the antithesis to individualism was popularized by P. Leroux and J. Reynaud in their *Encyclopédie nouvelle* and in their other writings, and by 1840 had come to be used freely in Europe to describe the schools of Saint-Simon, Charles Fourier, Owen and others who attacked the existing system of commercial competition and put forward proposals for a new way of life based on collective control. Later, these early schools of socialism were categorized by Karl Marx and Friedrich Engels as "utopian socialism," in contrast with the "scientific socialism," based on the materialist conception of history, of which they were the pioneers.

Later writers, delving back into the past, found anticipations of socialist doctrine in many earlier theorists, and applied the name over a wide field—for example, to Plato among the ancients, to a number of medieval writers, to Sir Thomas More (*Utopia,* 1516), T. Campanella (*City of the Sun,* 1623) and other utopia makers, and to such 17th-century social critics as the curé Jean Meslier in France and the Digger Gerrard Winstanley (*The Law of Freedom,* 1652), Peter Chamberlen (*The Poor Man's Advocate,* 1649) and the Quaker John Bellers in England. Among 18th-century writers the name is applied to Gabriel Bonnot de Mably (*Entretiens de Phocion sur le rapport de la morale avec la politique,* 1763) and Morelly (*Code de la nature,* 1755), the foremost critics of economic and social institutions among the philosophers who prepared the way for the French Revolution.

Among those who took part in the Revolution the name socialist is given to Jacques Pierre Brissot (1754–93), the Girondin leader, and sometimes to Jacques René Hébert, and above all to François Noel (Gracchus) Babeuf (1760–97), leader of the Société des Égaux, whose unsuccessful attempt to overthrow the Directory government in 1796 is commonly regarded as the starting point of the modern socialist movement. Babeuf's revolutionary group set forth the first practical program, and the *Manifeste des égaux* was the first socialist pronouncement. Babeuf and his followers regarded socialization of land and industry as necessary to complete the revolution begun in 1789. They proclaimed the equal natural right of all men to the enjoyment of the goods provided by nature, the universal obligation to labour, the universal right to education, and the necessity of abolishing both riches and poverty in the interests of human happiness.

Babeuf sought to establish his system by revolution carried through under a revolutionary dictatorship. His ideas were popularized later by his collaborator, Philippe Michel Buonarroti (1761–1837), whose *Conspiration de Babeuf* (1828), translated by James Bronterre O'Brien, influenced the English Chartists. His views on landed property had something in common with those of the British 18th-century land reformers (Robert Wallace, 1697–1771; William Ogilvie, 1736–1819; Thomas Spence, 1750–1814; and Thomas Paine, 1737–1809), but he went far beyond them in the amplitude of his social designs. Spence is nearest to him, and the Society of Spencean Philanthropists, formed by Spence's followers in 1816, can be claimed as the first organized socialist body in Great Britain. Spence stood for the collective ownership of the land by local communes, which would take over the government and provide by federation for the simple needs of administration under a communal system. Paine, on the other hand, was not a socialist, but a social reformer who, apart from his doctrines about land, anticipated many modern social service projects in part ii of his *Rights of Man.*

Nor can William Godwin (1756–1836) be rightly described as a socialist. In his *Political Justice* (1793) he declared for the abolition of all government, and advocated a free society in which property would go to those who could make the best social use of it. Godwin believed in the possibility of a completely rational social system without government, based on right education in moral and social principles. He inspired much later socialist as well as anarchist thinking, and had a considerable influence on Owen's ideas as well as on those of the British radicals of the 1790s, including Wordsworth, Southey and Coleridge in their early days. Shelley's *Prometheus Unbound* was largely based on the ideas of Godwin, whose daughter he married.

2. The Saint-Simon and Fourier Doctrines.—Socialist thought took a quite different turn with the comte de Saint-Simon (1760–1825), a French aristocrat whose outlook was formed not only by the French Revolution but also by a keen awareness of the impending revolution in industrial technique and in the role of science in human affairs. Saint-Simon held that the new social forces that had been unloosed by political revolution and scientific advance called imperatively for planned organization and control in the general interest, and was the first to see clearly the dominant importance of economic organization in the affairs of modern society and to grasp the concept of economic evolution as the key factor in social adjustment. In his most important works (*Introduction aux travaux scientifiques du XIX^e siècle,* 1807; *Nouvelle Encyclopédie,* 1810; *De la Réorganisation de la société européenne* [with the historian Augustin Thierry], 1814; *L'Industrie,* 1816–18; *Nouveau La Politique,* 1820; *Catéchisme des industriels,* 1823–24; *Nouveau Christianisme,* 1825) he put forward, not a system, but a series of originative ideas which were worked up by his disciples into a system. He stood, not for a struggle between employers and workers, but for a community among the productive classes against the parasitic nonproducers, on a basis of social ownership of the means of production and their administration by men of the requisite scientific and business knowledge. He believed in unequal rewards,

corresponding to real differences in quality of service, and in the conferring of large powers on a directing authority constituted on a basis of merit. The state, he held, was under an obligation to provide work for all, and all were under an obligation to labour for society according to their powers. Saint-Simon vigorously denounced the exploitation to which the labourer was subject under the existing system of property rights, and anticipated Marx in holding that the property relations sustained by any social order conferred upon it its essential character. He believed that human society tended in the march of history toward a system of universal association, which would be the guarantee of peace; and he regarded the Roman Catholic Church as having been a step toward this association. Holding its doctrines outmoded, he put forward in his *New Christianity* (1825) a nontheological religion for the new era, based on science and expressing his faith in a "science of sciences"—a field of thought in which he was the predecessor and inspirer of Auguste Comte. Saint-Simon's great contribution to socialist thought was his insistence on the duty of the state to plan and organize the use of the means of production so as to keep continually abreast of scientific discovery, and his insistence on the master function of the industrial experts and organizers, as against the politicians and the mere "men of business," in the society of the future.

Charles Fourier (1772–1837) was a younger contemporary of Saint-Simon. His first book, *Théorie des quatre mouvements*, was published in 1808 and was followed by others in which he repeated and expanded the same ideas (*L'Association domestique agricole*, 1822, revised as *Théorie de l'Unité universelle*, 1841; *Le Nouveau Monde industriel et sociétaire*, 1829; *La Fausse industrie morcelée*, 1835–36). Fourier is best known as the advocate of the *phalanstère*, a form of co-operative settlement which he believed to be the essential unit of social organization. It was to consist of 1,500 or 1,600 persons—a number which Fourier held to be the minimum for securing a right mingling of the many different tastes and temperaments. It was to be at once a working unit and a community of persons living together in a single great building; but the members were not to be equals in income or status, and each was to be rewarded for his own share in the common labour. Moreover, Fourier accepted property rights, providing for the division of the total product five-twelfths to labour, four-twelfths to capital and three-twelfths to special talent. His proposed division was in fact more favourable to labour than this makes it appear; for he advocated a very high rate of interest on small investments of capital, falling very sharply as the amount belonging to any one holder increased. In effect, he contemplated that most people would be capitalists as well as workers.

Fourier's system rested on the belief that most forms of labour could be made highly attractive if they were rightly organized, and that no one need, or should, be made to work at anything except of his own free will. He held that everyone should have many different jobs, never spending more than an hour or two consecutively at the same work, and that all work should be organized by groups or series of workers, between whom there would be natural emulation to do well. He stressed the predominance of intensive agricultural and horticultural work both over other forms of agriculture and over manufacturing labour, which he believed should be cut down to a minimum by making things to last and by the elimination of unnecessary products. The "dirty work" he said should be done by children, to whom it could be made attractive by the spirit of emulation and service. He advocated education through doing things rather than through learning about them, and gave children a large part in the work of his utopia. He stood for the equality of men and women, regarding the advancement of women as the crucial test of social progress.

Fourier's theories were based throughout on a psychological approach. He believed that civilization erred in seeking to repress the passions, which could by right social organization, under his system, be allowed to work beneficently, as God had meant. He claimed that his system would work without any need to change human nature, which he regarded as immutable. Fourier's methods of expounding his doctrines were often fantastic, but men found much sound sense in his writings. He was entirely opposed to state action for the establishment of his system, holding that its basis must be wholly voluntary, and believing this to be possible because he thought he had discovered the form of association that really fitted in with men's natural desires. Though usually regarded as a socialist, he is in reality rather the ancestor, jointly with Owen, of voluntary producers' co-operation.

Both Saint-Simon and Fourier were the inspirers of influential schools of thought. The disciples of Saint-Simon created a formal school, headed after his death by Saint-Amand Bazard (1791–1832) and Barthélemy Prosper Enfantin (1796–1864), who separated when Enfantin developed the religious sides of his master's doctrine on extravagant lines, including a form of community living which involved "free love." This aberration over, Enfantin, like others influenced by Saint-Simon (notably the famous engineer, Ferdinand de Lesseps), became a leading industrialist, while Comte went on to build his positive philosophy on Saint-Simonian foundations. Of Fourier's disciples, the most important was Victor Prosper Considérant (*La Destinée sociale*, 1834–38; *Manifeste de l'école sociétaire*, 1841), and in England Hugh Doherty (*The Morning Star*, 1840). In the United States Fourier greatly influenced Albert Brisbane (1809–90), C. A. Dana, Horace Greeley, Margaret Fuller, Hawthorne and Emerson; and the famous Brook Farm community (1841–47), described in Hawthorne's *Blithedale Romance*, was largely Fourierist in inspiration.

3. Owenism.—Robert Owen (1771–1858), generally regarded as the founder of British socialism, had much in common with Fourier, but approached the social problem from an essentially different angle. A highly successful master cotton spinner, at the head of the great factory at New Lanark which he made a model for good labour conditions, Owen was a powerful critic of the manufacturing system introduced by the Industrial Revolution and of the exploitation of labour which it involved. He denounced competition as leading necessarily to this exploitation, and advocated in its place a co-operative system based on villages of co-operation in which men and women would work and live together on a basis of communal enjoyment of the fruits of labour in both field and factory. Fourier advocated differences of individual payment and the allowance of interest on capital. Owen was prepared to allow interest until the owners of capital voluntarily gave it up, as he believed they would; but he favoured fully communal living in his villages and elsewhere payment to producers on a basis of "labour-time" instead of money—that is, of the time necessary for the various kinds of work, which Marx later called "socially necessary labour time."

The basis of Owen's doctrine was that the social character of men (*i.e.*, their social behaviour) is made for them and not by them: it is the product of environment and education and can be changed by improving these things. He was led to denounce all established religions because they taught that men were responsible for their evil doings, instead of attributing them to bad environment, and he set out to preach social rather than moral reformation. These views were first expounded in Owen's *New View of Society* (1813–14) and more fully in his *Report to the County of Lanark* (1821). They came into prominence after the end of the Napoleonic wars, when Owen appealed to the government both for factory legislation to protect the workers and for state action to cure unemployment by setting up villages of co-operation. Unlike Fourier, Owen did not exclude state action: he appealed first to the state and then, when it failed to respond, next to private philanthropists and subsequently to the working classes directly.

Owen's views attracted a large working-class following. From about 1830 to 1834 he was in effect the leader of a vast trade union movement aiming at the emancipation of labour by setting up co-operative productive societies, labour exchanges (for the exchange of the products of different trades on a basis of labour time), and great national associations, such as the Guild of Builders, designed to take over whole industries. On the collapse of this movement in 1834 Owenism remained the creed of a substantial body of followers, who turned back to the attempt to establish villages of co-operation. Some of these had been tried already—New Harmony, in the U.S., in 1825; Orbiston, in Scotland, in 1826;

and Ralahine, in Ireland, in 1831. A last Owenite community was started at Queenwood, in Hampshire, in 1839, on a basis that incorporated some elements of Fourier's doctrines. It failed in 1845; and Owenism thereafter gradually faded away, giving place on the one hand to secularism and other forms of "rational religion" and on the other to the great successful movement of consumers' co-operation, instituted in 1844 by the Rochdale Society of Equitable Pioneers, who were ardent Owenites. (*See* CO-OPERATIVES.)

Meanwhile, in France, Fourier had a successor in utopia building in Étienne Cabet (1788–1856), author of *Voyage en Icarie* (1840) and of an unsuccessful attempt to found a community in Texas and later in Illinois. Cabet's work was much influenced by Sir Thomas More's *Utopia*. It presented the picture of a perfectly symmetrical state, owning all the main industries and dividing the product on a basis of equality. Cabet's rulers were to be chosen by popular election, but were to have large powers, analogous to those of Saint-Simon's industrial leaders. Cabet borrowed some of the features of Fourier's *phalanstères*, but departed from Fourier in laying great stress on the state and on uniformity of dress, status and behaviour among the citizens. Like Saint-Simon, he put much emphasis on the role of science and, like Fourier, on education, which, with Owen, he regarded as the means of training children in the right social ideas. Pending the establishment of Icaria, he was a strong advocate of minimum wage laws and of progressive taxation of the rich. (*See* UTOPIAN COMMUNITIES.)

4. First Anticapitalist Writers.—Cabet was the last of the group of utopia makers who represent socialism in its first phase of evolution. Saint-Simon, though contemporary with this group, does not belong to it; and Owen is notable not only as a utopia maker, but even more as a leader of great working-class movements and an acute critic of the doctrines of orthodox political economy. In this last field he was the first of a group of writers who took the accepted principles of classical economics and based on them anticapitalist or socialist deductions. Owen's *Report to the County of Lanark* in many respects anticipates Marx; and Owen's leading follower in the realm of theory, William Thompson (1785–1833) (*Principles of the Distribution of Wealth Most Conducive to Human Happiness*, 1824), develops further the doctrine that, as labour is the sole true source of value, the labourers by hand or brain should receive in common the entire product, to be distributed on a basis of the greatest practicable social equality. Thomas Hodgskin (*Labour Defended Against the Claims of Capital*, 1825; *Popular Political Economy*, 1827; *The Natural and Artificial Right of Property Contrasted*, 1832) similarly turned the doctrines of the Ricardians against capitalism, but, following Godwin, arrived at anarchist rather than socialist conclusions about the new social order. Apart from Godwin, the sequence of British anticapitalist writers began with Charles Hall (*The Effects of Civilisation*, 1805) and continued with the Spencean Thomas Evans' *Christian Polity* (1816), Piercy Ravenstone's *Doubts on the Correctness of Some Opinions Generally Entertained on the Subject of Political Economy* (1821) and John Gray's *Lecture on Human Happiness* (1825). The Christian Owenite John Minter Morgan contributed *On the Practicability of Mr. Owen's Plan* (1819), *The Revolt of the Bees* (1826) and *Hampden in the Nineteenth Century* (1834); and William Thompson followed up his magnum opus with *An Appeal of One-Half the Human Race* [women] (1825), *Labour Rewarded* (1827) and *Practical Directions for the Establishment of Communities* (1830). T. R. Edmonds' *Practical, Moral and Political Economy* (1828), John Gray's *The Social System* (1831), J. F. Bray's *Labour's Wrongs and Labour's Remedies* (1838–39) and Mary Hennell's *Outline of the Social Systems and Communities Founded on the Principle of Co-operation* (1844) are the other leading works of the British Owenite and anticapitalist schools. Most of these writers mingled socialist deductions from Ricardian economics with ingredients drawn from Owen's co-operative doctrines. Bray wrote in England, but was born in America.

After the collapse of the Owenite trade-union and co-operative movements in 1834, the emphasis in Great Britain shifted to Chartism, with its demand for parliamentary reform based on manhood suffrage and annual parliaments. *The People's Charter*, published in 1838, crystallized this program, behind which was the driving force of acute economic distress arising out of the new Poor law of 1834 and the prolonged industrial depression that began in the 1830s and continued into the "hungry '40s." Chartism, resting on economic distress, had no clearly defined economic program: it was a hunger revolt, without much theoretical basis in its early stages. Under the leadership of Feargus O'Connor (1794–1855) it developed in the 1840s a "back-to-the-land" program based on individual peasant holding in collectively acquired land settlements (O'Connorville, Charterville), as against the Owenite advocacy of collective tillage in villages of co-operation. The Chartist land scheme collapsed in 1848, and thereafter Chartism broke up into a number of sects, with which it will be more convenient to deal later.

5. Christian Socialism.—There had been in England in 1848 and the following years a movement for what was called "Christian socialism" (*q.v.*) but was in fact co-operativism. This was mainly due to John Malcolm Ludlow (1821–1911) who had been much influenced by Philippe Buchez, Louis Blanc and the development of co-operative workshops in France, and succeeded in enlisting John Frederick Denison Maurice (1805–72), Charles Kingsley (1819–75), Edward Vansittart Neale (1810–92), Thomas Hughes (1822–96) and others in support of a movement to set up similar workshops in England, on a definitely Christian basis. The English Christian socialists were moved by horror at the appalling conditions prevailing in the workshops and factories and at the un-Christian spirit of the spreading industrial system, but were skeptical of the Chartist remedy of political reform. Kingsley announced that in his view the "French cry, Organization of Labour" was worth a dozen of the *People's Charter*. Immediately, the Christian socialists set out to establish small working associations which they financed, in the hope of sowing the seeds of a new social order. These soon failed; but they were led to give great help to the growing consumers' co-operative movement, especially in securing for it a legal status under the Industrial and Provident Societies act of 1852. Later, the Christian socialists made many further attempts to foster producers' co-operation and also to secure the acceptance of profit sharing and copartnership in capitalist industry. They also transferred their activities to education, founding the Working Men's college in London (1854); but by the later '50s the Christian socialist movement, as such, had practically ceased to exist.

Christian socialism developed also on the continent, in somewhat different forms, largely connected with the Roman Catholic Church. In France, its forerunner was Bishop Claude Fauchet (1744–93), the Girondin, who preached a form of Christian communism at the time of the Revolution. Hugues Félicité Robert de Lamennais (1782–1854), co-founder of *L'Avenir* (1830–32), can also be regarded as a forerunner (*Paroles d'un croyant*, 1834). Buchez, as we have seen, influenced Ludlow, and there has always been in France a Catholic social movement with some affinity to Christian socialism. The movement, however, developed much more strongly in Germany, partly under the influence of the Protestant Victor Aimé Huber (1800–69), founder of the Association of Christian Order and Liberty and leading advocate of co-operative production, and partly under that of the Roman Catholic bishop Baron Wilhelm Emmanuel von Ketteler (1811–77), who also advocated co-operative production as a means of curing the ills of capitalism and promoting reconciliation of classes. The movement spread to Austria and Belgium, but, like English Christian socialism, it belongs rather to the realm of social reform than to that of socialism in the usual sense of the word.

Also on the borderline of socialism is the German economist, politician and landowner Karl Rodbertus (1805–75) (*Social Letters*, 1850–51; *Illumination of the Social Question*, 1875), who expounded the subsistence theory of wages and the labour theory of value, and proposed state action to increase the labourer's share in the product by preventing the owners of capital from appropriating the fruits of rising productivity. Rodbertus regarded society as in process of evolution from the wage system to one in which the means of production would be publicly owned, and private

property would survive only in respect of income, which would correspond to the value of each man's labour. He also threw much light on the theory of economic crises, and considerably influenced the later formulation of Marx's ideas.

A much more central figure in the development of German socialism is Ferdinand Lassalle (1825–64), founder of the Universal German Working Men's association (*Allgemeiner Deutscher Arbeiterverein*) (1863), the first organized German Socialist party, in opposition to the Liberal party headed by Franz Schulze-Delitzsch. Lassalle, who was a great orator, caused this body to spread with extraordinary rapidity, but he was killed in a duel the year after its definite formation. It languished in his successors' hands and was finally fused in 1874–75 with the rival Marxist Social Democratic party formed in 1866 under the leadership of Wilhelm Liebknecht (1826–1900) and August Bebel (1840–1913). Lassalle laid great stress on the "iron law of wages," *i.e.*, the theory that wages tended under capitalism always to subsistence level, and attacked proposals for credit associations, consumers' co-operative societies and similar bodies as useless to help the workers in face of this inexorable law. Instead, he urged that "the working class must become itself a monster employer," not in little producers' co-operative societies, but by taking over large-scale industry "in the massed and concentrated form of the factory, with its enormous advantage in productivity." As the workers could not do this by voluntary action, it was necessary to invoke the power of the state, which "exists only to expedite and assure the march of culture." The state should place the necessary credits at the disposal of the associated workers, who should proceed to take the conduct of industry into their own hands, and should receive, in addition to their wages, dividends based on the profits of the several collective undertakings. The state, says Lassalle, "is the consolidated people"; but it can be made an instrument for the proposed change only by universal and direct suffrage, which must therefore be won by means of universal association and agitation. Under universal suffrage, the state will stand ready to execute the people's will (*Open Letter to the German Working Men's Association*, 1863). Lassalle was thus an advocate of socialization, to be achieved by means of political agitation and action, through a democratization and democratic conquest of the machinery of the state. But he was also, pending this democratization, ready to appeal to the existing state to extend help to the workingmen's associations. He discussed his plans with Bismarck, who undoubtedly learned something from Lassalle both in constituting the German Reich and later in introducing the social measures sometimes called "Bismarckian state socialism."

6. French Socialism.—While Chartism was running its course in Great Britain, socialism was taking on new forms in France after the revolution of 1830. The revolt of the Lyons weavers in 1831 is often regarded as the starting point of the French proletarian movement; and under the monarchy of Louis Philippe began the insurrectionary career of Louis Auguste Blanqui (1805–81), who passed more than 40 years in prison for various conspiracies. Blanqui, whose essential writings were collected in 1885 as *La Critique sociale*, was the successor of Babeuf in the advocacy of the seizure of power by a revolutionary minority, which would at once proceed to institute a socialist system. He organized conspiracies in 1836 and again in 1839. Released in 1848, he promptly attempted a new conspiracy, and was in prison until 1859. In 1861 he was again imprisoned for four years. In 1870 he headed the extreme left in Paris, but was imprisoned by Louis Thiers before the Commune, in which his followers played an important part. Blanqui's theories of revolutionary dictatorship contributed much to the French syndicalist doctrine of *la minorité consciente*, but were opposed by the Marxists, with their rival theory of mass dictatorship of the proletariat as a whole.

Blanqui was always the leader of small groups of ardent socialist revolutionaries. Under Louis Philippe, the main body of French working-class and socialist opinion followed, not him, but either Louis Blanc (1811–82) or Pierre Joseph Proudhon (1809–65). Blanc can be claimed in many respects as the forerunner of modern social democratic doctrines. His most important work, *L'Organisation du travail* (1839), demanded that the state should give full recognition to the "right to work," and should provide capital for "national workshops" to be managed collectively by the workers under public ownership. In the revolution of 1848 Blanc became a member of the provisional government, but was unable to get his ideas carried into effect, the so-called "national workshops" started by his opponents being mere relief works which were meant to fail so as to discredit his proposals. Blanc went into exile when Louis Bonaparte came to power, and spent many years in England, writing a series of important books on British social and political conditions. His other main socialist writings are *Le Socialisme: droit au travail* (1849); *Catéchisme des socialistes* (1849) and *Histoire de dix ans, 1830–40* (1841–44). Blanc was the originator of the socialist formula "From each according to his abilities: to each according to his needs." He stands for a socialism resting on public ownership, combined with workers' control in industry, and for a democratic parliamentary system as the instrument of socialist advance.

The idea of co-operative workshops, without that of state control, was also actively urged in the 1830s by the follower of Saint-Simon, Philippe Buchez (1796–1865), who became the foremost advocate in France of Christian socialism and largely inspired the English Christian socialists. His views are embedded in his periodical, *L'Européen*, and in his *Essai d'un traité complet de philosophie* (1839) and *Traité de politique et de science sociale* (1866).

Much more important than Buchez was that singular genius, P. J. Proudhon (1809–65), whose work belongs essentially to the history of anarchism rather than of socialism. From *Qu'est-ce que la propriété?* (1840), with the startling answer "*La Propriété, c'est le vol*" ("Property Is Theft"), to *De la capacité politique des classes ouvrières* (1865), Proudhon poured out a spate of books in which he mingled devastating criticism of the institutions of capitalism with emphasis on the inherent capacity for self-organization of the working class. He became the leading advocate of *mutuellisme*, whether it took the form of co-operative societies or labour banks or trade societies, or any form of working-class organization in which might be descried the germ of the classless, nongovernmental society of the future. Proudhon called himself a socialist as an opponent of capitalism and individualism and private property; but his positive doctrine always laid the main stress on personal freedom and voluntary association in a society freed from the tyranny of monopolist property rights. He favoured personal property and inheritance under a moralized system of property rights designed to exclude exploitation, and laid great emphasis on the abolition of interest and the provision of free credit to the producers. His best-known books, in addition to those already cited, are *Système des contradictions économiques ou, Philosophie de la misère* ("The Philosophy of Poverty") (1846), which provoked a famous reply from Marx: *Misère de la philosophie* ("The Poverty of Philosophy") (1847); *Confessions d'un révolutionnaire* (1849); *Idée générale de la révolution au XIX^e siècle* (1851); *La Révolution sociale* (1852).

Proudhon was addicted to complicated logical arguments, based largely on the idea of inherent "contradictions" in capitalist society. He used, or, as Marx held, misused, the Hegelian dialectical method extensively. He was not a system maker but a critical and suggestive writer of great force. Marx classed him as a *petit bourgeois*, because he had little grasp of historical evolution or of the power of great industry, and because his mutualist doctrines were taken up by the declining class of small-scale producers and were inapplicable to large-scale capitalist conditions. Proudhon's ideas had great influence on the development of French syndicalism and he ranks, with Mikhail Bakunin, as the principal philosopher of 19th-century anarchism.

II. KARL MARX AND HIS INFLUENCE

Up to the 1840s socialism developed almost exclusively as a French and British movement. Industrial evolution was much more advanced in Great Britain than elsewhere; and France had been, from the 18th century, the principal seedbed of revolutionary political ideas. In Germany, which was politically divided and economically much more backward, socialism began as a movement when the more radical followers of Georg Hegel came into

contact with advanced French social ideas in the course of the '30s and '40s. Johann Fichte (1762–1814) has sometimes been claimed as an ancestor of German socialism, because he exalted, as a nationalist and a social reformer, the claims of the state; but there is no substance in this view, unless all statist doctrines (including modern national socialism) are to be regarded as socialist.

German socialism really begins with the materialist philosophy of Ludwig Feuerbach (1804–72), who much influenced Marx, and with the "left" Hegelians, such as Bruno Bauer (1809–82), Moses Hess (1812–75) and Karl Grün (1817–87). Beginning as a realist or materialist critique of religion and of the established German philosophy (*see* Karl Marx and Friedrich Engels, *German Ideology*), this "left" Hegelianism, in which Marx was brought up, broadened out under French influence into Marxist "scientific socialism," taking the materialist conception of history, first clearly formulated by Karl Marx (1818–83) and Friedrich Engels (1820–95) in the *Communist Manifesto* of 1848, as its essential foundation. This famous manifesto, the starting point of the modern socialist and communist movements, was issued in the "year of revolutions," 1848, by the Communist league, which Marx had created on the basis of the German societies of exiles that had been preaching various forms of utopian socialism from the late '30s. Wilhelm Weitling (1808–71) (*Guarantees of Harmony and Freedom*, 1842) was the principal leader of this pre-Marxist German socialist movement, but was pushed out of the way by Marx and Engels as a moralist-utopian as soon as they had formulated their essential ideas. The League of the Just (1836–47) gave place to the Communist league, which at its congress in Dec. 1847 authorized Marx and Engels to draft the *Communist Manifesto*.

1. The Communist Manifesto.—This most celebrated of all socialist documents is the first clear proclamation of the revolutionary role of the proletariat, or working class. It sets out from an interpretation of all human history as a sequence of vast class struggles for power. Behind these struggles, and as their cause, lies the development of the "powers of production," or, in other words, of man's command over the forces of nature. Every stage in this development demands a corresponding organization of social forces for its exploitation—a particular arrangement of property rights and class relationships, sustained by an appropriate political and ideological system. This political and ideological system, however, though it is used to enforce obedience to the class conditions required, is not their cause but their result. The driving force lies in the powers of production themselves; and, as these develop, a disharmony arises between them and the social and political structure based on what they were at an earlier stage. This disharmony expresses itself in class struggles and leads to social revolution, which, when it comes, rapidly destroys the obsolete social structure and replaces it by a structure in harmony with the changed needs of the time. Such social revolutions involve and include revolutions in ideas as well as in institutions: they are the major turning points of human history.

Marx and Engels were far from supposing, as some of their critics have taken them to suppose, that all historical events could be explained in terms of this formula. It applies only to the great revolutions of history, and not to day-to-day events outside moments of historic crisis. Nor did Marx and Engels ever suggest that men are moved only by economic or self-interested motives. That is not the point, which is that, whatever may be the motives that move men, they are impelled by historical necessity to adapt their social structures and ideas to the requirements of the development of the powers of production. "Man," Marx writes, "always makes his own history," but he goes on to say that man makes it within the limiting conditions set by the problems and material realities of his own time and place.

The *Communist Manifesto* throws out, on the basis of this conception of history, a resounding challenge to the governing class, which is warned that the proletarian revolution is on the march. It includes also a searching criticism of other schools of socialists who fail to take their stand upon the principle of the class war. The work of the utopian socialists is passed under review; the followers of Proudhon are castigated; adverse comment is passed on Christian socialism and on the so-called "professorial socialism" which was becoming fashionable among a school of German economists. The communists, on the strength of their understanding of the historical role of the proletariat, put themselves forward as the natural leaders of the coming revolution, and sweep aside the *petit bourgeois* radicals whom they regard as in process of being rapidly superseded by the development of economic forces. This is not meant as an adequate summary of the *Communist Manifesto:* there is no space to deal with it adequately. All that can be attempted is to select the points most important for the history of socialism.

The defeat, in Germany and all over Europe, of the revolution of 1848 naturally involved a setback for European socialism. The Communist league disappeared; the leaders of socialism were again scattered and mostly in exile. But from this time on Marxism, though not yet fully developed as a system, found adherents in most of the leading countries. In England it influenced the later stages of Chartism, which became more consciously socialist as it ceased to be a mass movement. Of the Chartist leaders the three who have some claim to a place in socialist history are George Julian Harney (1817–97), Ernest Charles Jones (1819–69) and James Bronterre O'Brien (1805–64). Harney, who first published the *Communist Manifesto* in England, was a revolutionary who looked back to 1789 and regarded the proletarian revolution as the necessary completion of the French. He was influenced by Marx, but presently Marx discarded him as too unstable, and transferred his hopes to Ernest Jones, who became the principal English exponent of Marxism in his speeches and journals (*Notes for the People*, 1851–52; *The People's Paper*, 1852–58). O'Brien, also much influenced by the French Revolution and especially by Babeuf, never became a Marxist. Originally an Owenite, he developed into a state socialist, looking forward to nationalization of the land, public utilities and industries subject to monopoly. His principal work is his unfinished "Rise, Progress and Phases of Human Slavery" (in *Reynolds' Political Instructor* 1849, republished 1885). By 1860 Chartism in these later forms had flickered out, and socialism hardly existed in England except in the form of sympathy for utopian socialism in the writings of John Stuart Mill and some other leading economists.

2. The First International.—Meanwhile Marx, in London, had published in 1859 his *Critique of Political Economy*—virtually an advance sketch of *Capital*, and containing a plain exposition of the essentials of the materialist conception of history. The first volume of *Capital* appeared in 1867—the only volume published during Marx's lifetime. But before this Marx had succeeded in bringing into existence in London the International Working Men's association, or "first international" (1864) (*see* INTERNATIONAL, THE), consisting at the outset mainly of continental exiles and British trade-union leaders who sympathized with foreign revolutionary aspirations, however little they were disposed to foment revolution in their own country. The project of an international association had come in the first instance largely from the followers of the liberal nationalist leader Giuseppe Mazzini; but Marx succeeded in pushing them aside and in securing a body ready to follow his own lead. He drafted the address and statutes, and soon branches were founded in a number of European countries including Germany, France, Belgium, Italy, Switzerland and Spain. The new international played a considerable part in the labour troubles of the later '60s in France and elsewhere; and the outbreak of the Franco-Prussian War in 1870 found it active all over western Europe. In France and Belgium it was at first largely dominated by the followers of Proudhon and the Belgian collectivist socialist Jean Guillaume César Alexandre Hippolyte Colins (1783–1859) in Germany by the Marxists, in Italy and Spain and parts of Switzerland by the anarchists, of whom the Russian Mikhail Bakunin (1814–76) became the acknowledged leader. The first international held congresses in London (1865), Geneva (1866) Lausanne (1867), Brussels (1868), Basel (1869) and, after an interval caused by the war, at The Hague (1872). Its statutes and addresses were widely drawn, to attract adherents from a number of different schools; and its general council was composed largely of British trade-union leaders, who left the running to Marx and the group of exiles he had gathered round him. In 1867 there was

a struggle between the Marxists and the followers of Proudhon, who were driven out; and thereafter until 1871 Marx was practically in control.

The testing time for the first international came with the proclamation of the Paris Commune in 1871, after the defeat of France by Prussia and the fall of Napoleon III. Marx had advised his French followers against the rising, but when it took place he rallied at once to its defense. In Paris, members of the first international took part in the Commune side by side with the followers of Blanqui and of Proudhon. The Paris Commune was the first occasion on which the working class actually achieved political power, albeit only for a few weeks; and the rising was of immense symbolic importance for socialists everywhere. Marx, in the manifesto upon it (published as *The Civil War in France*, 1871) which he wrote in the name of the international, seized on its significance for the strategy of socialism as a whole. The proletariat, he held, could not assume power merely by taking over the existing apparatus of the bourgeois state. It needed to break the old state in pieces and to construct in its place a new proletarian state of its own. He praised the Communards for what they had done in this way, while criticizing them for having proceeded too slowly and too mildly to meet the need. At a time when the entire capitalist world was denouncing the Commune for its revolutionary excesses, Marx stressed rather the hesitancy and the clemency with which the proletariat had employed its new power.

There was acute controversy in socialist and labour circles about the Paris Commune. Marx's defense was too strong meat for many of the English trade-union leaders who had hitherto lent their names to the International Working Men's association; and in all countries the more timid or reformist adherents of socialism were scared off. The defeat of the Commune by Thiers and the reactionary French national assembly which wiped it out in blood was fatal to the international, already torn asunder by the dispute between the Marxists and the anarchist, or antipolitical, followers of Bakunin. At the Hague conference of 1872 Marx, in order to get rid of what had become an embarrassing child and to prevent its appropriation by the followers of Bakunin, obtained a vote removing the seat of the international to the United States, where, after lingering nominally for a few years, it was ingloriously wound up. The followers of Bakunin maintained for a time their rival international in Europe; but it struck no lasting roots except in Spain.

The question posed by Marx in connection with the Paris Commune—should the proletariat aim at conquering the bourgeois state in order to use it as the instrument of proletarian power, or should it set out rather to destroy the bourgeois state and replace it by a new, proletarian state of its own?—continued to divide the socialist movement. This very question came to a head when it was proposed, a few years after the Commune, that the German followers of Marx and of Lassalle should combine to form a single Social Democratic party. Lassalle, as we have seen, had stood for the conquest and use of the state, which he had regarded as needing only to be based on universal, direct suffrage in order to become an instrument of social progress. Marx, on the other hand, held that the bourgeois state was incapable of such conversion, and indeed that every state was essentially a class institution, made in the image of a particular ruling class—so that each class, on coming to power, would need to break the state of its predecessor and make a new state of its own as the instrument of its "dictatorship." This is the theory of the dictatorship of the proletariat, which the Bolsheviks claimed to apply in the Soviet Union after 1917.

3. Social Democracy.—Liebknecht and Bebel, Marx's leading supporters in Germany, were not prepared in 1875 to jeopardize union with the Lassalleans by insisting on this principle. The Gotha program, on the basis of which the German socialist forces were united in that year, accepted by implication Lassalle's view of the state. Marx, to whom the draft was sent, protested violently in a memorandum to the German Social Democrats (subsequently published as *Critique of the Gotha Programme*); but the leaders in Germany actually suppressed his criticism, and pushed the amalgamation through. The German Social Democratic party thus came to birth with a contradictory set of objectives. Most of the language of its program was that of Marxism, but embedded in it was the objective of winning power by taking over the control of the bourgeois state, rather than by overthrowing it, together with an advocacy of co-operative production on the lines proposed by Lassalle. In effect, the German Social Democratic party became a parliamentary party, aiming at the assumption of political power by constitutional electoral means. Its leadership, however, was in the hands of men who regarded themselves as devout Marxists but who refused to accept the dictatorship of the proletariat as part of the essential Marxian doctrine.

This was of vital importance for subsequent socialist history, for over most of western Europe German social democracy became the model on which national Social Democratic parties were organized. In France Jules Guesde (1845–1922), after several years of agitation, was joined by Marx's son-in-law Paul Lafargue (1842–1911) in founding the Marxist Parti Ouvrier Français in 1880. In Belgium the followers of César de Paepe (1842–90) formed a similar party, but closely linked up with the trade-unions and co-operative societies, in 1885. In Spain Pablo Iglesias (1850–1925) created a Marxist party, in rivalry to the anarchists, in 1879. In Scandinavia, the Danish party dates from 1879, the Norwegian from 1887, the Swedish from 1889 and the Finnish (the first to secure a parliamentary majority) from 1899. The Italian Socialist party dates from 1892, the Polish Socialist party from the same year and the Dutch Social Democratic party from 1894. The Russian Socialist party was founded, as the Emancipation of Labour group, by G. V. Plekhanov (1856–1918) and P. B. Axelrod (1850–1928) in 1883. Thus Marxian socialism spread over Europe during the final quarter of the 19th century. In some countries, such as Russia and Poland (mainly under Russian rule), the political conditions made parliamentary activities impossible, and the parties maintained a decisively revolutionary and underground character. In most countries, however, they became national parliamentary parties, compelled by the exigencies of electioneering to put forward programs of social reform to be pressed for in advance of the full conquest of political power and the establishment of a socialist system.

In Great Britain the attempt to establish a Marxist party was made by Henry Mayers Hyndman (1842–1921), who was chiefly responsible for founding the Democratic federation in 1881. This body had at first only a semisocialist program, as it was attempting to attract into its ranks the radical workingmen's clubs which had followed Charles Dilke and Joseph Chamberlain in their radical phase. But in 1884 the federation became the Social Democratic federation and adopted a completely Marxist program. The same year it split, William Morris (1834–96), the socialist poet and artist, and others, with the support of Engels, breaking away to form the Socialist league. Neither of these bodies attracted a large following; but their influence was felt indirectly in the great outburst of strikes among the less skilled workers about 1889 and in the formation of new trade-unions, with a largely socialist outlook, among the dockers (London dock strike 1889), gasworkers and other classes of previously unorganized workers.

At the same time there arose among the miners, under the leadership of James Keir Hardie (1856–1915), a movement for the legal minimum wage and the legal eight-hour day, backed by the newly formed Miners' Federation of Great Britain (1888). The socialists, notably John Burns (1858–1943) and Tom Mann (1856–1941), placed themselves at the head of the less skilled workers, adding the demand for the "right to work" to those for the minimum wage and the eight-hour day. Hitherto British trade-unionism had been for the most part attached to the Liberal party under W. E. Gladstone; but from the late '80s there arose a widespread movement for independent labour representation, and the local bodies formed on this basis joined forces in 1893 in the Independent Labour party (I.L.P.) under the leadership of Keir Hardie, with an evolutionary socialist program. Powerfully reinforced by the *Clarion*, founded in 1891 by Robert Blatchford (1851–1943), whose *Merrie England* (1894) sold more than 1,000,000 copies, the I.L.P. set out from the first to induce the trade-unions to enter politics on the socialist side. In 1900 it was successful in bringing into existence the Labour Representation

committee as a federation of trade-unions and socialist bodies, but without a fully socialist program.

4. Fabianism.—We must now retrace our steps to 1884. The Social Democratic federation, after the split, fell almost completely under Hyndman's control and pursued a narrow and doctrinaire form of Marxism which alienated the trade-unions interested in immediate reforms and drove one working-class leader after another out of its ranks. Morris' Socialist league, which had seceded partly as a protest against Hyndman's dictatorial methods and partly because it objected to the running of Socialist candidates aided by Tory gold in order to split the Progressive vote, turned wholly antipolitical and was captured by anarchists, who drove William Morris out of it and deprived him of his paper, the *Commonweal,* in which originally appeared his socialist romance, *News From Nowhere* (1891).

In the same year as the Socialist league (1884), the Fabian society was founded, of which Sidney Webb (1859–1947) and George Bernard Shaw (1856–1950) speedily became the outstanding leaders. The Fabians were a small group of intellectual socialists, standing for an evolutionary conception of socialism in sharp contrast with Marxism and endeavouring, by progressive reforms and the nationalization and municipalization of industries, to turn the existing state into a "welfare state." The name they adopted was derived from that of the Roman general known as Fabius the Delayer because of his deliberate, long-range strategy. They declared themselves the inheritors of the Benthamite tradition of promoting "the greatest happiness of the greatest number," and maintained that this principle now pointed to extensive state intervention as plainly as it had once seemed to point to *laissez faire.* In *Fabian Essays* (1889) and in a host of well-informed Fabian tracts the society laid down its essential doctrine and the practical applications of it; and the Fabians also proclaimed a policy of "permeation," by which they meant a readiness to get their ideas taken up by any party or person that would listen to them. Their work considerably influenced the policy of Keir Hardie's Independent Labour party, and their hold on the working-class movement was strengthened by the careful and constructive studies of trade-unionism and other working-class organizations carried out by Sidney Webb in collaboration with his wife Beatrice Webb (1858–1943). The Fabians can be regarded as the group which first clearly worked out the philosophy and practical implications of that form of "gradualist" socialism which became in practice the policy of the Labour and Socialist parties in most of the countries with parliamentary constitutions, whatever theoretical doctrines they continued to proclaim as the basis of their faith. (*See* further FABIAN SOCIETY.)

5. Socialism in the U.S.—In the United States, socialism followed a different course. After the decline of Owenism and Fourierism, which had at one time a considerable hold, socialism practically died out. The single tax doctrines of Henry George (1839–97) obtained a large following in the 1870s and helped to prepare the way for socialism, which was reintroduced mainly as the doctrine of immigrants from various European countries, each bringing with him his particular brand. Largely under German influence, the Socialist Labor party was formed in 1877 and ran its first presidential candidate in 1892. It continued to grow until 1898; but then came a split, Daniel De Leon (1852–1914), its leader, insisting on its duty to form a socialist trade-union movement in opposition to the American Federation of Labor, which was strongly antisocialist. De Leon was a Marxist of the extreme left, following Marx's view of the state and the necessity for the dictatorship of the proletariat, and his attempts at industrial unionism were the forerunners of the later attempt to create the Industrial Workers of the World (1905) (*q.v.*), with the difference that De Leon aimed at industrial unionism closely linked with a revolutionary Socialist Labor party, whereas the Chicago I.W.W., led by W. D. ("Big Bill") Haywood, was antipolitical and syndicalist in outlook. In 1901 the seceders from De Leon's S.L.P. joined forces with other groups to form the American Socialist party, under the leadership of Eugene V. Debs (1855–1926), and the new party soon greatly outnumbered the S.L.P., polling nearly 1,000,000 votes for Debs in the presidential election of 1912.

III. LATER NATIONAL DEVELOPMENTS

1. France.—In the 1880s and 1890s the developing Socialist parties in western Europe were being compelled to define their political attitudes. In France, the Parti Ouvrier had split in 1882 into two sections, Guesdists, or Marxists, and Possibilists, the followers of Paul Brousse (1844–1912), with a more moderate program. The Possibilists split again in 1890, when a left wing broke away under Jean Allemane (1843–1935). The followers of Blanqui held together in a separate Comité Révolutionnaire Central; and yet another party, the Independent Socialists, grew out of a group originally created in 1885 by Benoît Malon (1841–93), the author of an extensive *History of Socialism* (1881–84) and the apostle of *Le Socialisme intégral*—the title of his best known book (1891–92). The Independent Socialists attracted a group of highly influential leaders, including among them Jean Jaurès (1859–1914) and Alexandre Millerand (1859–1943). All these groups wooed trade-union support; but the French trade-unions, under the influence of Fernand Pelloutier (1867–1901), held aloof from politics and went over gradually to the doctrines of revolutionary syndicalism and direct action, which were definitely proclaimed, with the general strike, as its policy at the Lyons congress of 1901. This tendency was already well established when, in the middle 1890s, all France was set in turmoil by the Dreyfus affair. This famous affair caused a big reorientation of political forces, including the establishment in 1899 of the ministry of "republican defense" of Pierre Marie René Ernest Waldeck-Rousseau, in which the socialist Millerand was offered and accepted office. The ensuing dispute led to the regrouping of French socialism in two rival parties, the Parti Socialiste de France (Guesdists and Blanquists) and the Parti Socialiste Français (Broussists, Allemanists and Independents), the latter supporting the participation of socialists in a progressive capitalist government. The split lasted until 1905, when the rival parties joined forces in the Parti Socialiste Unifié, under Jaurès, which pursued a stormy course up to the outbreak of World War I in 1914. The assassination of Jaurès, the outstanding leader of French socialism, on the eve of war in that year was a severe blow to French socialism and opened the door wide to fresh dissensions.

2. Germany.—The rift in French socialism occurred on the practical question of socialist participation in a capitalist government. In Germany the dispute, with the same fundamental basis, took a different form. In 1891 the German social democrats, in their new Erfurt program, eliminated the Lassallean clauses of the Gotha program of 1875. In 1899 Eduard Bernstein (1850–1932) published *Die Voraussetzungen des Sozialismus*, translated under the title *Evolutionary Socialism*, in which he declared the need for a fundamental revision of Marxist doctrine. Bernstein had lived long abroad, first as an exile in Switzerland and from 1888 as correspondent in London of the Social Democratic *Vorwärts;* and he had been greatly influenced by Fabianism and by the British Independent Labour party. Bernstein denied the imminent collapse of capitalism, the progressive crushing out of the middle classes, the concentration of capital in fewer and fewer hands, the "increasing misery" of the working class and the necessarily reactionary character of the state. He affirmed the importance of working for immediate social reforms rather than for revolution, and asserted that the gradual movement toward socialism was everything, and the ultimate goal of socialism in effect nothing. He attacked the orthodox formulation of the materialist conception of history and emphasized the importance of noneconomic and moral factors in the making of social change; and he regarded the Marxian theory of value as a merely abstract concept remote from actual conditions. Finally, he denied that the industrial proletariat could hope, by itself, to conquer political power and, relying on parliamentarism as against dictatorship, pleaded for a moderate socialism which could be regarded as the heir of liberalism and for an appeal to men and women of all classes rather than to the workers alone.

The demands of "revisionism" led to a tremendous controversy, in which Karl Kautsky (1854–1938) appeared as the principal champion of Marxist orthodoxy. The revisionists were defeated at the congress of the German Social Democratic party, and the

letter of Marxism was faithfully preserved. But in practical politics the German Social Democrats to an ever increasing extent accepted Bernstein's precepts, though the very limited elements of democracy in the German constitution greatly limited their practical influence and effectively prevented them, up to 1918, from being confronted with any such problem of participation in the government as had disturbed the French Socialists in 1899.

3. The Second International.—The rise of national Socialist parties in the leading countries was followed by attempts to create a new socialist international. Periodical international socialist congresses were held from 1889; and in 1900 the International Socialist bureau (the second international) was set up to act as a permanent link between the national parties. Unlike the first international, however, it was not a centralized body claiming to dictate policy to its sections, but a loose federation of independent parties, each claiming to follow its own line in accordance with national conditions. It was much occupied with the questions of antimilitarism and the prevention of war, but refused to endorse the policy of the general strike against war sponsored mainly by the French, and succeeded only in passing ambiguous resolutions which furnished little practical help in the crisis of 1914.

4. Syndicalism.—The years immediately before World War I were a period of great labour unrest in many countries. They were marked by a reaction against parliamentary social democracy, by a rapid growth of trade unionism in various forms and by the development of new doctrines of direct action and syndicalism radiating mainly from France. The French syndicalists proclaimed the preponderance of economic over political power, and contended that parliamentarism necessarily involved compromise and a weakening of the will to revolution. The workers, they maintained, must fight their battle on their own terrain—that of industry—by strike action, which could be used to secure political as well as industrial concessions. They must act alone, without invoking the aid of politicians, and must take as their aim the transference of industry into their own hands. The French syndicalists, influenced by Proudhon and Pelloutier, looked forward to the reorganization of France into self-administrating communes under the control of the workers' *syndicats* and *unions de syndicats*, loosely federated nationally and internationally on a basis of pure "workers' control." They were strongly antimilitarist and antipatriotic, favouring the general strike both as a measure against war and as a means of accomplishing the social revolution. In the hands of certain theorists, notably Georges Sorel (*Réflexions sur la violence*, 1908) and Hubert Lagardelle (*Le Socialisme ouvrier*, 1911), the general strike was elevated to the rank of a "social myth," powerful in inspiring the workers to resolute action, even if it never happened in the form supposed.

This syndicalist doctrine owed much to anarchism and had much in common with the anarchist-communism of the great Russian revolutionary Prince Peter Kropotkin (1842–1921), author of *Fields, Factories and Workshops* (1898), *Mutual Aid, a Factor of Evolution* (1902) and other books of wide international influence. It was much like the doctrine maintained in Spain by the Iberian Anarchist federation (F.A.I.) and the Spanish National Confederation of Labour (C.N.T.). Transplanted to the U.S., where capitalism was much more advanced and centralized, it assumed a different form, the attempt to form a single, all-inclusive big union, designed to overthrow capitalism by revolutionary direct action, and to take the great industries into the workers' hands through the Industrial Workers of the World. In Great Britain it appeared in an industrial syndicalist movement led by Tom Mann (*The Industrial Syndicalist*, 1912) and in a modified form in guild socialism, an attempt to reconcile state socialism with the syndicalist doctrine of "workers' control." (*See* SYNDICALISM.)

5. Guild Socialism.—First preached by A. R. Orage (1873–1934) and S. G. Hobson (1868–1940) in the *New Age* about 1911, guild socialism (*q.v.*) spread rapidly during World War I, under the auspices of the National Guilds league. The guild socialists stood for state ownership of industry, combined with "workers' control" through delegation by the state to national guilds including all the workers by hand and brain and organized internally on democratic lines. About the state itself they differed, some believing that it would remain more or less in its existing form, and others that it would be transformed into a federal body representing guilds, consumers' organizations, local government bodies and other social structures (G. D. H. Cole, *Guild Socialism*, 1920; S. G. Hobson, *National Guilds and the State*, 1920). Guild socialism was much stimulated during World War I by the rise of the left-wing shop stewards' movement, demanding "workers' control" in the war industries. After the war, the building workers, led by Hobson and Malcolm Sparkes, founded building guilds which built houses for the state; but after the slump of 1921 the state withdrew financial help, and the movement collapsed. The shop stewards' movement also disintegrated when the war ended; and the guild socialist movement fell to pieces, leaving behind it an effect in the incorporation of some element of "workers' control" into the programs of trade unionism and of the Socialist and Labour parties.

6. The War Issue.—Over most of the world, World War I sharply divided the socialist forces. In Great Britain, France and Germany the majorities in the Social Democratic and Labour parties supported their respective countries, whereas in Italy and Russia the majorities were against the war. In Great Britain there was no formal split, but the Independent Labour party, while remaining part of the federally organized Labour party, opposed the war. In Germany, in 1915, the Social Democratic party virtually split, a minority breaking away to become the "Independents," under Kautsky and Hugo Haase, and a group further to the left, the *Spartakusbund* (Spartacus union), appearing a little later under Karl Liebknecht (1871–1919) and Rosa Luxemburg (1870–1919), one of the principal latter-day theorists of Marxism (*The Accumulation of Capital*, 1913). In France, *majoritaires* (for the war) and *minoritaires* (antiwar) waged incessant conflict without positively forming rival parties. In Italy Benito Mussolini broke away from the Socialist party to lead a militant prowar group, which formed the nucleus of the Fascist party. In Poland Jozef Pilsudski, previously a Socialist, sided with Germany in the hope of securing Polish liberation from Russia, while Rosa Luxemburg's followers, who had formed a Polish Social Democratic party in 1893, sided with the Bolsheviks in opposing the war.

IV. RUSSIAN SOCIALISM

The outbreak of the Russian Revolution in 1917, followed by the Bolshevik revolution later in the year, exercised a deep influence on the socialist movement throughout the world. Russian socialism, at the time of the revolution, was divided into four main parties—Socialist Revolutionaries, Left Socialist Revolutionaries, Bolsheviks, and Mensheviks.

1. Socialist Revolutionaries.—Conditions in Russia were so different from those in western Europe that Russian socialism had followed a largely independent course. The earlier Russian exponents of socialism, Aleksandr Herzen (1812–70), Peter Lavrov (1823–1900) and Nikolai Chernyshevski (1828–89), sought to apply western socialist ideas to Russian conditions, whereas Bakunin applied ideas that were indigenously Russian to the conditions of the west. Herzen believed that the survival of the commune as the basis of Russian village life made Russia, despite its industrial backwardness, an appropriate country in which to institute the socialist revolution, which he conceived as above all else a peasant revolution. Chernyshevski developed these ideas, regarding the overthrow of tsarism and the landlord system and the institution of political democracy as the first steps toward agrarian communism. Lavrov (*Letters on History*, 1868–69), the philosopher who inspired the Narodnik (People's) movement among the Russian intellectuals, preached a gospel of self-devotion by the educated classes to the cause of the people, and then looked forward to the achievement of socialism by the leavening of the people with socialist ideas, which could be built on the foundations of the communal tradition of Russian village life. Out of the Narodnik movement sprang the Narodnaya Volya, the idealist movement of organized terrorism which was responsible in 1881 for the assassination of Alexander II. This in turn was the precursor of the Socialist Revolutionary party, which came into formal existence

in 1901 and, representing many different tendencies, was by far the largest of the Socialist parties at the time of the revolution of 1917. From it split off, under M. Spiridonova, the Left Socialist Revolutionary party, which joined the Bolsheviks in the second revolution, and for a short time occupied a place in the soviet government.

2. Social Democrats.—As against the Socialist Revolutionaries, whose main appeal was to the peasants, the Russian Social Democrats had their strength among the urban workers. Russian factories were relatively few, even in 1917, but the few were mostly very large and used mass-production methods. The urban proletariat was small, but highly concentrated, and lived under conditions of intense exploitation. We have seen how in 1883 Plekhanov and Axelrod took the lead in setting up in Geneva the Emancipation of Labour group, based partly on local societies established inside Russia in the '70s. This group spread the knowledge of Marxism in Russia. In 1895 Vladimir Ilyich Ulyanov (Lenin; 1870–1924) united the groups in St. Petersburg (Leningrad) into an Emancipation of Labour society, which put itself at the head of the industrial struggles then in progress. Out of this and other local bodies arose the Russian Social Democratic party, which was formed at Minsk in 1898 but did not take definite form until after the foundation of *Iskra* ("The Spark") (1900), a social democratic journal published abroad in which Lenin collaborated with Plekhanov and Axelrod.

3. Bolsheviks and Mensheviks.—The second (and first real) conference of the Social Democratic party was held in Brussels and London in 1903. It adopted a revolutionary program largely drafted by Lenin, including an assertion of the rights of national self-determination, a series of demands for land reform in the interests of the peasants, and a pronouncement in favour of the dictatorship of the proletariat. A dispute arose over the conditions of admission to the party, Lenin demanding a closely knit, disciplined party, whereas the majority favoured open membership for anyone who accepted the declared principles. The leader of the majority against Lenin was Julius Ossipovich Zederbaum, known as Martov (1873–1923), subsequently the leader of the Mensheviks. But on the other issues Lenin's group won, and they were thereafter known as the Bolsheviks (majority) whereas Martov's followers were the Mensheviks (minority). In 1904 the split became definite, the Bolsheviks and Mensheviks holding separate congresses and organizing two rival parties. The basic difference was that the Mensheviks wished to create a Social Democratic party on the model of the national parties in western Europe, and to work in alliance with the bourgeois left for a democratic revolution, holding that the time for socialism in Russia would come when the country had passed through a regime of capitalist democracy, whereas the Bolsheviks wanted a centralized and disciplined party that would aim directly at power and would seek to rouse the peasant masses to rally to the side of the industrial proletariat. The Bolsheviks were prepared to work with the bourgeois left for democratic revolution, but set out to capture at once the leadership of the revolution and refused to make concessions to the *bourgeoisie* in order to enlist its help.

This is not the place to tell the story of the Russian Revolution —of the disintegration of the large but amorphous Socialist Revolutionary party, the conquest by the Bolsheviks of a majority in the revolutionary soviets of workers and peasants, and the crushing out of the Mensheviks on the Bolshevik assumption of power. (*See* RUSSIAN REVOLUTION.) What is relevant here is that the Bolshevik revolution was based on Lenin's interpretation of Marxism, putting in the forefront the dictatorship of the proletariat, the complete destruction of the old state machine and the creation of a new proletarian state as the instrument of the dictatorship (Lenin, *The State and Revolution*, 1917; *The Proletarian Revolution and Kautsky the Renegade*, Eng. trans., 1920). This view of Marxism was combated not only by the Mensheviks in Russia but also by most of the leading social democratic theorists in western Europe, notably Karl Kautsky (*The Dictatorship of the Proletariat*, 1918; Eng. trans., 1920), and by Émile Vandervelde (1866–1938), the Belgian president of the Labour and Socialist international, which was established in 1920 and reorganized in 1923 as the successor of the pre-1914 second international and continued its traditions practically unchanged, as well as by the British leaders.

The Bolsheviks sent out to the workers of the world a new *Communist Manifesto* (1919) and set out to organize a new third international—the way for which had been prepared by the antiwar international Socialist conferences held at Zimmerwald (1915) and Kienthal (1916), and by the attempt to organize a world conference at Stockholm in 1917—with the design of stirring up revolution throughout the world. At this stage it was widely believed that the Russian Revolution could not succeed in establishing itself unless it were speedily followed by socialist or communist revolutions in the advanced capitalist countries. Leon Trotsky (1879–1940), at that time Lenin's closest collaborator and the creator of the Red army, was especially associated with this view, which was part of his doctrine of "permanent revolution." Trotsky was also an advocate of rapid Russian industrialization as a means of consolidating the power of the revolution and an opponent of concessions to the peasants, which he held would delay this process.

4. Communism.—As developed theoretically by Lenin and later by Joseph Stalin (1879–1953) and others, communism was no new doctrine. It was Marxism, applied practically without change to the conditions of contemporary Russia. It could be so applied, because Russia in 1917 was still much like the countries of western Europe at the time when Marx and Engels formulated their essential doctrines. Western social democracy, while it retained its nominal allegiance to Marxism, had in fact so modified Marx's doctrines, especially about the state and dictatorship, as in effect to deny them. It had been working in practice for the peaceful democratic conquest of state power, and for an evolutionary socialism that would set out to use the existing state machine and to transform it gradually. The Russian socialists could not possibly have attempted so to use the tsarist state machine, as was plainly shown in the events that followed the abortive Russian revolution of 1905. They could only seek to overthrow it and to replace it either by a state modeled on western parliamentarism (the Menshevik policy) or by a state based on proletarian dictatorship (the Bolshevik policy). The western social democrats, wedded to parliamentarism, supported the Mensheviks and denounced the Bolsheviks as betrayers of democracy, whereas the Bolsheviks denounced them as counterrevolutionaries and traitors to the socialist cause.

The world revolution hoped for by the Bolsheviks did not come, but neither did the crushing out of the Russian Revolution by the capitalist countries. Through many vicissitudes, the Soviet power was able gradually to consolidate its strength. Trotsky was driven into exile; Stalin became the unquestioned leader and set out to, as he conceived of it, build up socialism within a single country under the successive five-year plans and the statute of nationalities, which conferred wide autonomy on the many peoples of the Soviet Union. In 1930 the policy of agricultural collectivization was taken seriously in hand, a form of village co-operative (the *kolkhoz*, or "collective farm") replacing individual peasant cultivation. Industrialization was vigorously pushed, and in World War II the Soviet Union plainly demonstrated its might and power of survival. In 1935 Sidney and Beatrice Webb, the theorists of Fabianism, surprised many by publishing their monumental work (*Soviet Communism: a New Civilisation*) largely in support of the policies and achievements of Russian Communism. This did not mean that they regarded the Soviet form of revolution as applicable to western Europe. They did, however, sharply differ from the social democratic theorists in regarding it as having justified itself fully under Russian conditions.

V. MODERN TRENDS

1. Western Europe.—In western Europe the end of World War I brought with it a great increase in the strength of the Social Democratic parties. In Great Britain, the Labour party had been up to 1918 only a small minority group. Profiting by the disintegration of liberalism, it reorganized itself in 1918 under Arthur Henderson (1863–1935) as a nationwide party standing for evolu-

tionary socialism (*see* its manifesto, *Labour and the New Social Order*, 1918, written by Sidney Webb). By 1924, under James Ramsay MacDonald (1866–1937), it formed the first (minority) Labour government, which lasted only a year. In 1929 it returned to office, again in a minority, but the second Labour government collapsed in the crisis of 1931, MacDonald seceding with others to form a "national" coalition government. During the 1930s Labour gradually regained strength. It remained a moderate, evolutionary socialist party, and was a partner in the war coalition formed in 1940. In 1945, in the election that followed hard upon the end of the European phase of World War II, the Labour party for the first time gained a considerable clear majority over all other parties, winning not only the industrial areas, but also most of the suburban residential districts near London and other big cities. Labour thereupon formed its third government, with a definite mandate for the policy of evolutionary socialism on which it had fought the election. This policy was set out in its manifesto, *Let Us Face the Future* (1945). In 1951 the Conservatives were returned and held control until 1964 when Labour won a very narrow parliamentary majority.

In Germany, the fall of the Hohenzollerns and the proclamation of the Weimar republic raised the Social Democrats to the position of the first party in the state. But they made no attempt to establish socialism and were soon involved in suppressing left Socialist and Communist groups. The German workers became disastrously divided into rival Social Democratic and Communist parties; and severe economic distress reinforced feelings of national humiliation in stimulating the rise of Adolf Hitler's Nazi, or National Socialist, party, which ultimately seized power in 1933. "National Socialism" (*q.v.*) was not a form of socialism, but its bitterest enemy. The so-called "Socialist" element in it consisted in its exaltation of the claims of the national state, regarded as a metaphysical being beyond good and evil, above all individual or sectional claims; but in practice it worked as the ally of large-scale capitalism and militarism and remorselessly crushed out all free working-class organization. It was the national state, organized to the limit for imperialist war and conquest—the very antithesis of the socialism described in this article. After 1939, however, Nazism won the allegiance of a few notable socialist renegades, such as the French neosocialist Marcel Déat.

Fascism (*q.v.*), of which Nazism was the German variety, made its first appearance in Italy, under the leadership of Mussolini. Italian socialism, which had opposed the war, adopted a semi-revolutionary line after 1918. The Italian workers in 1920 occupied the factories but made no attempt to turn their industrial struggle into a political revolution. Their defeat prepared the way for the march on Rome, by which Fascism seized power in 1922. Italian Fascism, like German Nazism, glorified the state, to which it professed to give a corporative form, based on corporations representing industries and professions. (*See* CORPORATE STATE.) In fact, behind this facade, it meant dictatorial control by the Fascist party, working in alliance with large-scale capitalism and suppressing all independent working-class or political organizations.

In France, after 1918, the communists were a majority in the Socialist party, which they converted into a Communist party. A large section broke away and reconstituted the Socialist party (known as S.F.I.O.—Section Française de l'Internationale Ouvrière), of which Léon Blum became the leader. In France, as in Germany, socialism was greatly weakened by the conflict between communists and socialists, and the position was made worse by the development of two rival trade-union movements. At length, in 1935–36, the trade-union split was healed, and both communists and socialists allied themselves with the radicals in the popular front. A wave of strikes followed, and many concessions were gained. But the front broke down, and French politics were in disorder at the outbreak of World War II. Following the collapse of 1940, most of the French socialists joined the resistance movements associated with Gen. Charles de Gaulle, and the communists, while maintaining their separateness, took part in the Gaullist and postwar coalition cabinets from 1944 to 1947. In the latter year they were excluded from the government.

In Spain, where the working-class forces were traditionally divided between socialists and syndicalists (with a strong anarchist element, chiefly in Catalonia), a popular front, extending to the radicals, achieved power in 1931, but was overthrown in the ensuing civil war by the Fascist counterrevolution under Gen. Francisco Franco, supported by Germany and Italy, while the western parliamentary countries stood aloof. The U.S.S.R. gave some help, but on conditions that split the socialist forces. In Austria, where the Social Democrats, headed by Otto Bauer (1881–1938), a leading theorist of the movement, were the strongest party in Vienna but had little hold on the Catholic countryside, a Catholic semi-Fascist dictatorship was set up by Engelbert Dollfuss in March 1933, and in Feb. 1934 a rising of the Viennese workers was crushed and the Socialist movement was disrupted or driven underground. In 1938 the Nazis seized Austria and incorporated it in "greater Germany," applying the entire apparatus of suppression.

The social democratic movement enjoyed its only successes between the wars in Scandinavia, especially in Sweden, where, under the leadership of Karl Hjalmar Branting (1860–1925) and later of Per Albin Hansson (1885–1946), it carried through a moderate policy of liberal semisocialism with considerable economic success. Denmark had a similar experience; and in Norway, where socialism was on the whole farther to the left, much progress was also made. The Scandinavian parties made no attempt to introduce socialism, but adopted advanced policies of social reform and economic planning without disturbing the institutions of capitalist property. Their fortunate economic position made this possible to a degree not possible elsewhere. In eastern Europe, under the tutelage of the U.S.S.R., Socialist parties by mid-century had disappeared or had been absorbed by the Communist parties.

2. North America.—In the U.S., socialism remained backward. (*See* SOCIALIST PARTY [U.S.].) The U.S. Communist party took away a good deal of the former support of the Socialist party, but failed to gain a really large following. The American Federation of Labor remained strongly antisocialist and even more anticommunist, refusing all association with the trade-unions of the U.S.S.R. The newer Congress of Industrial Organizations, which arose in 1935 as the result of a breakaway from the A.F. of L., had a more leftist though hardly less anticommunist policy, but did not result in the growth of any nationwide Labour party, although Labour parties arose in a few states, notably New York. The U.S. produced no great socialist thinker, though Upton Sinclair became world famous for his socialist novels (*The Jungle*, 1906; *The Brass Check*, 1919; *Oil*, 1927) and there was much acute social criticism, notably in the work of Thorstein Veblen (1857–1929) (*Theory of the Leisure Class*, 1899; *Theory of Business Enterprise*, 1904). In Canada, socialism made advances after the establishment in 1932 of the Co-operative Commonwealth federation, the Canadian Labour and Socialist party, which appealed to farmers as well as industrial workers.

3. Australia, New Zealand, and South Africa.—In Australia the Labor party, based mainly on the trade-unions, was a powerful political force. It formed the government in 1941 and remained in power for eight years. In New Zealand the Labour party, having won the elections of 1935, remained in power until 1949. It returned to power in 1957 but only for three years. In South Africa, mainly because of the divisions between African and white workers, socialism made no headway.

4. The Far East.—In the far east, Chinese socialism began with Sun Yat-sen (1866–1925), the leader of the revolution of 1912, whose famous *Testament* is an application of socialist principles to Chinese conditions. The Chinese National party, the Kuomintang, was at the outset partly under socialist inspiration; but following the rise of a Communist movement in China, under Russian influence, there were violent dissensions leading to civil war (1929) until the Chinese communists came to power in 1949. The new regime, although closely allied to the Soviet Union and entirely dominated by the Communist party, was adaptable enough to use the services of noncommunists, including small capitalists as well as socialists, in many specialist services and branches of production. Great projects of industrial development were embarked upon with Soviet help, and rapid progress was made with

various forms of rural collectivization and co-operation. Many in the west hoped that Chinese communism would before long deviate sharply from the Russian model.

In Japan a Socialist party was formed in 1901 but was speedily suppressed, and there was renewed persecution during the Russo-Japanese War of 1904–05, which the socialists opposed. After 1918 there was for a time a renewal of socialist activity; but no stable socialist movement was established, and by the 1930s the movement had again been wiped out by militarist persecution, or driven wholly underground. Japanese socialism became politically important after 1945, establishing itself as the leading opposition force in the postwar parliament.

Meanwhile, in India, independence put into power a Congress party government, headed by Jawaharlal Nehru, himself a socialist; and this government's second five-year plan, issued in 1956, included large provisions for public investment as well as for welfare development. The Indian National Congress became formally committed to a sort of democratic socialism as a long-term objective, but continued to be largely under nonsocialist leadership and to claim to stand for national unity. The Indian Socialist party operated at first inside the Congress, but presently seceded from it and thereafter experienced considerably fluctuating fortunes and underwent a split in 1955, when a section headed by R. M. Lohia broke away from it. In 1964 the two groups merged to form a new United Socialist Party with a parliamentary representation of 21.

In the Arab countries substantial Communist and Socialist parties made their appearance; but nationalism remained the predominant issue, and the socialists were active mainly in the left wing of the various nationalist movements, though in Syria and Lebanon, as well as in Egypt, social questions—especially land reform—were forcing their way to the front.

In Indonesia the communists became a powerful opposition group; the socialists after playing a considerable part in the early years of independence subsequently lost ground. Burma established itself under broadly socialist rule. In 1964 Burma became a one-party state with the Socialist Program Party founded by Gen. Ne Win as the only authorized party.

The Asian Socialist parties, after refusing to join the postwar Socialist international, established an Asian Socialist international of their own, which entered into fraternal relations with it.

5. Contemporary Socialism.—The wartime alliance between the Soviet Union and the west temporarily eased animosity between European socialists and communists but did nothing to overcome their fundamental differences. Later, such factors as the communist seizure of power in Czechoslovakia, the Korean War, and Stalin's growing despotism caused further deterioration of this relationship. But the death of Stalin led to a substantial modification of Soviet totalitarianism by 1956, in which year the 20th congress of the Communist party of the Soviet Union was marked by a sharp denunciation of Stalin's methods and by a recognition of the possibility of advance toward socialism by nonrevolutionary methods in certain countries.

Immediately great debates opened both inside the Communist parties of all countries and among left-wing democratic socialists, who foresaw some prospect of improving international working-class relations and of further approaches toward world *détente*. As against this the western socialist parties and the Socialist international uniting them maintained their anticommunist vehemence. The suppression of the Hungarian revolution in Nov. 1956 suggested that the Soviet government was potentially as ruthless as ever and by hardening anticommunist feeling in the west thoroughly confused the over-all situation.

The issue of parliamentary democracy continued to occupy socialist thinkers. In Yugoslavia and, subsequently, Poland one-party rule appeared capable of substantial liberalization; nevertheless democratic socialists continued to stress the virtues of free elections and rival political parties. Doubtless these were indispensable wherever their traditions were established; it was not clear whether they could be insisted upon in countries lacking parliamentary experience and where nonrevolutionary advance was blocked by feudal and absolutist rule. Nor was parliamentary progress toward socialism possible in countries such as France and Italy where the working-class movement was divided into factions unable to co-operate in any way.

In September 1964 socialists met in Brussels, Belg., to celebrate the 100th anniversary of the founding of the first International. The secretary of the organization reported that it had affiliated with it 44 Labour and Socialist parties with a combined membership of nearly 12,000,000 persons. Parties affiliated with the International were in control of the governments of Great Britain, Denmark, Norway, Sweden, Israel, and the Malagasy Republic.

6. Interpretation of Socialism.—The foregoing historical account has been designed to describe the socialist movement by denotation, rather than to attempt any precise definition of socialism, which cannot indeed be accurately defined. Socialism is both a movement and a theory, and takes different forms under different historical and local conditions. It is fundamentally a movement aiming at a classless society based on the socialization of property in the essential instruments of production and appealing primarily to the working class as the exploited class whose historic mission it is to bring the class system to an end. This description (it is not meant as a definition) admits of many different views of the methods of social and economic organization appropriate to a socialist society and of the steps to be taken for its establishment.

Socialism can be either statist or libertarian, Marxist or "liberal," revolutionary or gradualist, cosmopolitan or only internationalist in a sense that lays stress on the importance of the national unit.

Marx drew a sharp contrast between "utopian socialism," basing itself on moral principles conceived as absolute, and "scientific socialism," resting on the materialist conception of history, with its corollary, the class struggle. As Marxism developed, the first great controversy was between the Marxist advocates of disciplined and centralized proletarian mass action and the anarchist (or later syndicalist) upholders of the theory of local mass spontaneity and federalist "free communism," sponsored by the followers of Bakunin and, in a less revolutionary sense, by those of Proudhon (the *mutuellistes*).

Still later, after the rise of social democracy, the controversy shifted to the question of whether socialists should set out to capture and use the existing state (Fabianism, evolutionary social democracy) or should seek to destroy the existing state and build up a new one by means of proletarian dictatorship (bolshevism, communism).

In these controversies, means and ends were mixed up together. It was partly a question of revolutionary versus evolutionary methods, partly a question of parliamentary democracy versus dictatorship, partly a question of libertarianism versus centralized state authority. Naturally, doctrines and emphasis varied from time to time and from country to country. Marxism, in its emphasis on the scientific basis of the materialist conception of history, tended at the extreme to throw over altogether the moral basis and to regard morality simply as a reflection of the forces of economic evolution. It is, however, difficult to see why anyone should trouble to work for socialism merely because he believes that it is in the line of historical evolution, or unless he also believes it to be good and that what is good ought to be pursued. Moral indignation is not the least of the weapons in Marx's own powerful armoury.

In essence, what Marxism opposes is the view that socialist judgments of value can be reached a priori, without taking account of the conditions of time and place. Man makes his own history; but the choices open to him are limited by the circumstances in which he has to act, and among these the condition of the "powers of production" holds a key place.

Socialism is essentially a movement for the promotion of the well-being and happiness of individual men and women (the "greatest happiness of the greatest number"), and not of any metaphysical entity such as the state, which should exist only to promote the ends of individuals. That these individuals are grouped in classes, and that social action in its major manifestations takes a class form in no wise invalidates this generalization, which is com-

mon to all schools of socialists (but not to "national socialists" or to some forms of so-called "Christian socialism"). Anarchist communism, social democracy and Leninist (though not Stalinist) communism all aim in their several ways at the establishment of a classless society and at the liberation of the human spirit, as well as at the abolition of physical want. Communist dictatorship, however perverted in practice, is intended only as a transitional measure, leading up to the "withering away" of the state. The ideal of world-wide human brotherhood and liberty is common to all schools of socialists, by whatever route they attempt to advance toward it. This holds good even for those socialists who reject "idealism" as a bourgeois doctrine and insist on speaking in terms of class rights and historical necessity rather than of humanistic ideals.

SOCIALIST PARTY (U.S.). On March 29, 1900, representatives of the Social Democratic Party of America, of which Eugene V. Debs (*q.v.*) and Victor L. Berger were leading members, met in New York city with representatives of the moderate branch of the Socialist Labor party led by Morris Hillquit, Max Hayes and others, and agreed to nominate Socialist candidates for president and vice-president in the 1900 campaign. Their nominees were Debs, former president of the American Railway union, for president, and Job Harriman, California attorney, for vice-president. The two groups waged a joint campaign that resulted in a vote of 96,878 for the Socialist ticket.

Following the campaign the two groups issued a call for a "unity convention" to be held July 29, 1901, in Indianapolis, Ind., with the view toward officially launching a united party. At this convention the older groups dissolved and formed the Socialist party to serve as "the party of the working class and those in sympathy with it" dedicated to the bringing about of "a system of collective ownership by the entire people of the means of production and distribution." The immediate demands in the party's platform included planks for woman suffrage, old-age pensions, unemployment insurance, health and accident insurance, the increase of wages, the reduction in working hours, direct legislation, and public ownership of public utilities.

During the next 11 years, from 1901 to 1912, the party grew steadily in numbers and influence. Its dues-paying membership increased from 16,000 to 118,000; its presidential vote, with Debs as candidate, from 96,000 to nearly 900,000; its representation in public office from zero to more than 1,000, including 56 mayors, over 300 aldermen, numerous state legislators and one congressman, Victor L. Berger from Milwaukee.

The year 1912 likewise found the party engaged in a vigorous internal struggle with the followers of William D. Haywood, leader of the Industrial Workers of the World (I.W.W.), who emphasized direct industrial action, including sabotage and the general strike, as a means to a co-operative social order, based on syndicalistic principles. The majority of the party adhered to their belief in parliamentary action and amended the constitution to exclude from membership advocates of sabotage and violence. In 1913 Haywood was expelled from the party's executive committee. The controversy led to the withdrawal of numerous "direct actionists" from the party.

In the following year, 1914, the European war broke out. Some Socialists felt that the United States should immediately enter the war on the side of the Allied powers. The majority took the position, as did millions of other Americans, that the United States should remain neutral and later offer itself as mediator or arbitrator, with a view toward bringing about a just and lasting peace. In 1916 the party nominated Allan L. Benson, writer and antimilitarist, as its presidential candidate and rolled up a vote of more than 585,000.

When the U.S. entered the war in April 1917, the Socialist party at its St. Louis convention declared "its unalterable opposition to the war just declared." During the next year many of the party's journals and meetings were suppressed by the government, and Debs was arrested for delivering an antiwar speech at Canton, O. and sentenced to a federal penitentiary for ten years. While Socialist activity came to a standstill in many parts of the country, it took on renewed vigour in other sections. In New York city, Morris Hillquit, Socialist candidate for mayor on a platform that called for an early and democratic peace, received a record vote of 146,000. He helped to bring into office ten assemblymen and seven aldermen.

On Nov. 7, 1917, the Russian Bolsheviks staged their successful revolution. Many members of the Socialist party were of the opinion that the United States was ripe for a similar revolution and urged the adoption by the Socialist party of Bolshevik tactics and the joining of the Communist International. To aid their cause, they swelled the party membership rolls with recent immigrants from countries of eastern Europe who were better ac-

quainted with the institutions of their homelands than with those of the United States.

The struggle over socialist *v.* communist tactics culminated in the Chicago convention of the party in late Aug. 1919. The left wing elements in the party were defeated and withdrew to form the Communist and Communist Labor parties. Though the party's membership during the struggle was greatly reduced (numbering 26,766 after the convention), the party's vote in 1920 with Debs, still in prison, again as its nominee, exceeded 900,000.

During the early 1920s labour was faced with widespread unemployment, with a concerted attack by employers on the trade union movement, and with attempts of the government to suppress civil rights. At the same time government corruption reached new heights. As a result of these and other conditions, many trade unions turned to independent political action as one method of fighting reaction and an unstable economy. In 1922 a number of leaders of organized labour, particularly in the railway trades, led by William H. Johnston, president of the machinists, formed a Conference for Progressive Political Action. Hillquit was invited to represent the Socialist viewpoint on the conference's governing board. The conference called with others a convention to meet in Cleveland on July 4, 1924, to nominate a Progressive presidential candidate. It nominated Sen. Robert M. La Follette of Wisconsin.

In his acceptance speech, La Follette expressed his belief that a new party would be born following the election. Socialists, seeing in this campaign the beginning of a Progressive or Farmer-Labor party, supported the La Follette ticket, which also received the endorsement of the executive council of the American Federation of Labor. Although the Progressive ticket received nearly 5,000,000 votes, no new party materialized and the Socialists returned to their traditional policy of supporting Socialist candidates, while continuing to work for a national farmer-labour political alignment.

Debs, five times Socialist presidential candidate, died in 1926, two years after the La Follette campaign. In the 1928 elections the party turned to Norman Thomas, writer, lecturer, former Presbyterian minister and co-executive director of the League for Industrial Democracy, as its new standard bearer. In that year, when many were predicting that the "new capitalism" was guaranteeing to the country permanent prosperity, Thomas received but 267,200 votes. Four years later, however, in the midst of the depression, his vote increased to 884,781.

During the next four years various factions developed within the party. They differed in opinion as to "the road to power" and the possibility of limited cooperation with the Communists in the fight against world fascism and reaction. This controversy led in 1936 to the withdrawal of several hundred party members and their organization of a Social Democratic federation. The 1936 convention decisively repudiated any political united front with the Communist party. During the next few years antagonism to the Communist party was progressively sharpened by the American Communists' support of Stalin's policies.

During this four-year period (1933–1936), the Franklin D. Roosevelt administration, in its drive to surmount the depression, embodied in its "New Deal" legislation many immediate demands of the Socialist party platform in the fields of social security, housing, public power and

labour-management relations. The enactment of section 7-a in the National Industrial Recovery act gave an impetus to labour in its drive to organize many of the giant industries, while labour leaders came into more cordial relationship with the president of the United States than ever before in the nation's history. As a result of these developments, many trade unions felt politically obligated to give active support to the Democratic administration, and made it increasingly difficult for their members to remain active in the Socialist party and other minority political groups. In the 1936 campaign, therefore, labour's support fell off and the vote for Thomas decreased to 187,720.

During the 1940s and 1950s the party continued to nominate presidential candidates—Thomas in 1940, 1944 and 1948, and Darlington Hoopes, Pennsylvania lawyer and former Socialist assemblyman, in 1952 and 1956. After the outbreak of World War II, and before Pearl Harbor, Socialists opposed America's entrance into the war. When war was declared by the U.S. the majority of Socialists gave it their critical support, while urging the maintenance of civil liberties, democratic controls over war and postwar collectivism and the winning of the earliest peace that promised permanency, followed by the establishment of an inclusive international organization.

In its presidential campaigns the party emphasized increasingly that its economic goal was not the public ownership of all industry, but an economy aimed at equality of opportunity in which public, co-operative and private ownership existed side by side. The 1956 platform urged "the ownership by genuine cooperatives and publicly owned and democratically managed corporations," of public utilities, banks, insurance companies and certain basic industries. Its immediate demands included the expansion of public educational, health, recreational, housing and social security services; the conservation of natural resources; the strengthening of labour legislation; the end of racial discrimination; economic and cultural aid to underdeveloped countries; and international agreements for disarmament with strict inspection and controls.

In 1957 the Social Democratic federation reunited with the Socialist party, forming the Socialist party-Social Democratic federation (S.P.-S.D.F.). Frank Zeidler, mayor of Milwaukee, was elected chairman of the executive committee. A few months after the merger the party was readmitted as a full member into the Socialist International. In 1958, emphasizing its increasing role as a political educational, rather than an electoral organization, the party voted to permit its individual members to enter the primaries of other parties and to support labour and avowedly progressive candidates of other political parties. In 1960 and again in 1964 the majority of the party decided against the nomination of a presidential candidate, but campaigned for the party platform, emphasizing the necessity of an honest, meaningful political realignment.

While the party's electoral successes have been less than its founders had hoped, since the beginning of the century the party has served, its advocates hold, as a potent educational force in social and political life. (H. W. L.; N. M. TH.)

SOCIAL SCIENCES. The social sciences are concerned with the orderly investigation of the behaviour of man in society with the aim of cumulating a body of relevant theory. Theories concerning group behaviour, whether economic, political, or social are legion. They are implicit in men's actions, transmitted in customary beliefs, and elaborated in literature. The distinctive quality of social science is that it attempts to formulate such theories unambiguously and in a way which permits the testing of theory against fact.

Method.—Much of the difficulty in science, contrary to popular misconception, is not to produce theory but to test it. For this reason social scientists tend to be as much concerned with method

as with result in their inquiries. Indeed what John Maynard Keynes said of economics is likewise true of all social science: "It is a method rather than a doctrine, an apparatus of the mind, a technique of thinking, which helps its possessor to draw correct conclusions." Moreover, though the social sciences may be defined as the study of man in society, it must not be concluded that this is held to be the only method available for the understanding of social phenomena. On the contrary, much insight into the nature of communities, associations, classes, nations, and races comes from the poet, the novelist, the traveler, and the moralist. The social sciences can claim a special place in the vast body of writing on social life only insofar as they aim to produce generalizations which are verifiable because they are arrived at by scientific procedures.

The lack of maturity of the social sciences compared with the physical and biological sciences is often attributed to the use of quantification in the latter and its relative absence from the former. Certainly science is refined by measurement, and the conversion into numbers of such concepts as social distance, moral density, or political allegiance sets peculiarly intractable problems. Nevertheless it must be recognized that the use of quantitative methods distinguishes the natural from the social sciences only in degree; such methods are used with conspicuous success in economics and demography, and statistical techniques form part of the indispensable equipment of all modern social scientists.

More generally it is characteristic of the modern development of the social sciences that they are modeled on the aims and methods of the natural sciences. What these aims and methods are remains, to some extent, a matter for debate and throughout the 20th century, especially in America, there has been much criticism of misguided imitation of the natural sciences in the quantitative pursuit of the trivial, the substitution of scientism for science, and susceptibility to "testomania and quantophrenia," as Pitirim A. Sorokin said in his *Fads and Foibles in Modern Sociology and Related Sciences* (1956). Nevertheless it is increasingly recognized that there is a unity of method in all generalizing or theoretical sciences which is sometimes called the hypothetico-deductive method and which is admirably expressed in the writings of Karl Popper, for example, in *Poverty of Historicism* (1957), *Logic of Scientific Discovery* (1959), and *The Open Society and Its Enemies* (1945).

"What is important to realise is that in science we are always concerned with explanations, predictions, and tests and that the method of testing hypotheses is always the same. . . From the hypothesis to be tested—for example a universal law—together with some other statements which for this purpose are not considered as problematical—for example some initial conditions—we deduce some prognosis. We then confront the prognosis whenever possible, with the results of experimental or other observations. Agreement with them is taken as corroboration of the hypothesis, though not as final proof; clear disagreement is considered as refutation or falsification." (Karl Popper, *Poverty of Historicism*, p. 132, Routledge and Kegan Paul, London, 1957.)

Three Examples.—This brief statement of the fundamentals of theory and method in all science, natural or social, may be illustrated by reference to three examples, one from economics, one from sociology, and one from political science. The first comes from Lord Keynes's *General Theory of Employment, Interest and Money* (1936). The pre-Keynesian or neoclassical theory of the level of employment and wages held (1) that the demand for labour is determined by the marginal product of labour and (2) that the supply of labour is determined by the marginal disutility of work. These two schedules when put together would determine the wage of labour and, in consequence, would assure full employment, apart from "frictional" and voluntary unemployment. From this theory it could be deduced that the mass unemployment in the United States in 1932, for example, must have been due basically to a refusal by the unemployed to accept wages corresponding to their marginal productivity. This deduction or prognosis, Keynes argued, was not supported by the facts. He therefore set to work to show that the classical postulate—that the general level of real (as distinct from monetary) wages is determined by the character of the wage bargain—was an illicit assumption which limited the validity of classical theory to the special case of full employment. He then tried to generalize the theory by putting forward a new hypothesis concerning the forces which determine the general level of wages, income, and employment, emphasizing, in particular, the level of effective aggregate demand. In the new theory some initial conditions—for example the skill and quantity of available labour and the existing technology—were taken for granted. The level of employment (and the national income) was then explained in terms of variations in three variables—the propensity to consume, the marginal efficiency of capital, and the rate of interest—which determine the rate of investment and saving. In contrast to "classical" theory, the rate of interest was explained not in terms of savings and investments but as a function of a new concept of liquidity preference together with the quantity of money. In this way it was possible to deduce the existence of underemployment equilibrium in an economy.

A second example may be taken from the work of the German sociologist Max Weber. His theory that the development of Western bourgeois capitalism was necessarily preceded by Calvinist and other Puritan religious movements as creators of indispensable psychological preconditions offers an illustration of theoretical advance by methods akin to those used in the natural sciences. Weber started from the then well-established Marxist theory of the genesis of capitalism through an emerging *bourgeoisie* seizing favourable opportunities for capital accumulation, the creation of a propertyless proletariat, and the exploitation of a new technology permitting factory production. He then extended the theory by showing that these "material" conditions, though necessary, were not sufficient. They existed elsewhere, whereas Calvinism or its equivalent social counterpart of capitalism did not. As a result Weber contributed to the cumulation of theory in the social sciences. From the point of view of method Weber's work is one of the best examples of the use of history as a kind of natural laboratory for the testing of a hypothesis. He first established, in his famous essay on "The Protestant Ethic and the Spirit of Capitalism" (1904), that there is a high degree of congruence between the ethic of Protestantism and the organization of economic activity in capitalist societies. He then turned to an immense comparative study of other religions and other civilizations to seek for the negative instance of indigenous capitalism without the ascetic spirit of Protestantism. Of course the vagaries of history could not provide more than a rough approximation to the rigorous controls of an experiment in chemistry, and the Weber thesis remains controversial; but the plan of the work is an impressive demonstration of Popper's doctrine of the unity of method in science.

The third example, taken from political science, begins with German economist and sociologist Robert Michels' "Iron Law of Oligarchy" expounded in his *Political Parties* (1911), which held that political parties and other membership organizations inevitably tended toward oligarchy, authoritarianism, and dictatorial leadership. This example again illustrates the paradoxical nature of science as advancing by looking backwards critically at the existing state of theory and specifying the limits within which its hypotheses are valid. Thus a later American study (Seymour M. Lipset, Martin Trow, and James Coleman, *Union Democracy* [1956]) produced a set of specific hypotheses concerning the factors which will support or undermine member participation and democratic control in private organizations and thereby showed the limited conditions under which Michels' law applies and replaced a somewhat vague generalization by a clearer set of related propositions. The later study also illustrates a method increasingly followed in social science in that it used the economy of investigating the deviant case in order to delimit application of a hypothetical generalization—in this case the International Typographical Union, as the one outstanding exception to the general rule among private organizations of government by one-party oligarchy. The results constituted another example of cumulative research, the purpose of the study being, as the authors remarked, "not to 'refute' Michels or other previous workers in this area, but rather to refine and build on their insights and findings, paying them the respect

of using them more often than we quote them."

Historical Origins.—All science can be traced back to antiquity. In the modern world the disparity of achievement between the natural and the social sciences is sometimes put down to the youth of the latter or, on a more sophisticated view, to the relatively small number of hours spent on it. But it is doubtful whether either explanation is borne out by the facts. What is certainly true, however, is that the sciences of man and of nature have been the objects of oscillations in the attentions of scientifically minded men. In the contemporary world the natural sciences are plainly dominant. From roughly the beginning of the 17th century the advance of first the physical and later the biological sciences has not only outstripped that of the social sciences but has been the basis of a continuous revolution in human life. There have been previous dramatic advances in the material and cultural conditions of mankind—for example the Neolithic revolutions of some seven or eight thousand years ago which gave men control over their food supply through the development of the techniques of cultivation—but none of these stages in social evolution are comparable, as judged for instance by their effect on population size, with the rise of modern industrial society based on the application of natural science. Nevertheless the relative importance accorded the social sciences is not inevitable and indeed it is arguable that, at least at one stage in the development of Greek science, the works of Plato and Aristotle had put politics ahead of physics.

The crucial period in the growth of the modern disparity between the sciences was the 150 years from the beginning of the 17th century. Scientific interests had penetrated but never dominated the humanism of the Renaissance. Niccolò Machiavelli's *Prince* (1513) stands out as a monument to the release of men's minds from medieval preoccupations and is still read by the modern political scientist. But, as natural scientists, Leonardo da Vinci, Tycho Brahe, Kepler, and Copernicus in the 15th and 16th centuries have to be seen as precursors of the great astronomers and physicists of the 17th century, above all of Galileo and Newton. Even in the 20th century the social sciences are often said to await a Galileo, and only mathematical economics is thought of as having passed through its Newtonian revolution.

Again it must be emphasized that the remarkable concentration of human intelligence on the sciences of nature in the century and a half after 1600 was not absolute. In the same period the Italian Giambattista Vico had published his *Principles of a New Science Dealing With the Nature of Nations, Through Which are Shown Also New Principles of the Natural Law of Peoples* (1725) in which he set out to study human history by the methods which Francis Bacon had proposed for the study of the world of nature. In Vico's *Scienza Nuova* we find, as Edmund Wilson has put it (*To the Finland Station*, Doubleday, p. 2, 1940), "the modern sociological and anthropological mind waking amidst the dusts of a provincial school of jurisprudence of the end of the 17th century and speaking through the antiquated machinery of a half-scholastic treatise." But Vico's vision was not shared by his contemporaries, and his work was left to be rediscovered by Jules Michelet a century later. Similarly in England in the 17th century the scientific pursuits of the Royal Society had as a minor theme the study of human life by similar principles of empirical science. Sir William Petty's population studies, John Graunt's analysis of mortality rates in the London plague, and Edmund Halley's construction of the first life table mark the beginning of an English tradition of "political arithmetic" which, adding moral and administrative concern for the consequences of urban industrialism to its scientific interests, has flourished down to the present day.

However, the beginnings of modern social science may be traced directly to the 18th-century Enlightenment with the first flowering of rationalism in France and the stern pursuit of a secular moral philosophy in Scotland. The revival of interest in society at this time also illustrates the general truth that social science is the child of social change. The rise of capitalist society, with its attendant social upheaval of urban growth, industrialism, and mobility of men and ideas, imparted a powerful impetus to social inquiry. In France, through the work of the physiocrats, economics was launched as an empirical science, and in books like Voltaire's *Age of Louis XIV* (1751) the notion of progress was involved in the study of history and society in a way which broke sharply with medieval thought and to a degree which was unshaken until the rise of functionalism in anthropology at the beginning of the 20th century. The second half of the 18th century also saw notable advances in Scotland by a remarkable group of moral philosophers connected with the Scottish universities, including Adam Smith, John Millar, Francis Hutchison, and Adam Ferguson—all influenced by a growing mood of skepticism and empiricism in philosophy, of which perhaps the greatest exponent was David Hume. Adam Smith's *An Inquiry Into the Nature and Causes of the Wealth of Nations* (1776) remains, with Karl Marx's *Das Kapital* (1867) and Alfred Marshall's *Principles of Economics* (1890), to this day among the great comprehensive treatises in economics, but the Scottish moralists also contributed in their lesser-known works some of the foundations of modern sociology, psychology, and anthropology. Thus, for example, John Millar's *Observations Concerning the Distinction of Ranks in Society* (1771) is probably the first scientific analysis of social stratification, and Adam Ferguson's *An Essay on the History of Civil Society* (1767) is an admirable early example of the comparative study of social institutions.

Specialization and Synthesis.—In the 19th century the location of initiative in the social sciences shifted from Scotland to Germany and other continental European countries. During the course of the century what would now be thought of as the main divisions of social science—economics, anthropology, sociology, political science, and social psychology—began to emerge and, toward the end of the century, to receive academic recognition. The 19th century was also characterized by an opposite tendency toward the construction of a synthesis of social science, especially at the hands of Auguste Comte, Karl Marx, and Herbert Spencer.

In economics the first three-quarters of the century was devoted to the building of the synthesis of theory known as "classical economics"—a term invented by Marx to refer to Ricardo and his predecessors but which was later extended to include also the followers of that tradition, notably John Stuart Mill and Alfred Marshall. This phase came to an end with the clarification of the doctrine of marginalism (*see* ECONOMICS: *The Marginal Utility Analysis*). In the last quarter of the century attention was transferred to methodological problems—especially to the *Methodenstreit* controversy in Austria and Germany between Karl Menger and Gustav von Schmoller, the latter asserting that economics could be no more than a historical science in the sense that its laws could only apply to the unique circumstances of particular historical periods; the former insisting on the status of economics as a theoretical science searching for universal laws governing the behaviour of supply, demand, price, and the level of employment. The victory of Menger's point of view has since proved to be an emancipating force not only for economics and economic history in Germany but for the social sciences everywhere. On the other hand the models of rationality (*e.g.* "economic man") which permitted conspicuous advances in 19th-century economics left problems for the 20th-century development of theory in the social sciences, particularly that of finding a place for the nonrational determinants of human behaviour. For the most part these tasks fell to sociology and psychology, but economic theory itself was also extended to include problems of choice and expectations through applications of the mathematical theory of games.

The 19th century also saw considerable advances in those branches of the social sciences which were oriented more toward biology and history. The social scientists of this period inherited the 18th-century achievements of Linnaeus and Bouffon in the classification of living organisms and the Lamarckian hypothesis that the hierarchy of species was due to a natural process of evolution. In seeking to classify and date types of culture and to formulate generalizations concerning the social evolution of man, scholars like Lewis Morgan (*Ancient Society* [1877]) in the United States, Herbert Spencer (*Principles of Sociology* [1876–96] and *Descriptive Sociology* [1873–1934]), Sir Henry Maine (*Ancient Law* [1861]), and Sir Edward Tylor (*Primitive Culture*

[1871]) in England, Johann Bachofen (*Das Mutterrecht* [1861]) in Switzerland, and Friedrich Ratzel (*Völkerkunde* [1885]) in Germany laid the foundations for modern comparative anthropology and sociology. Spencer gave modern sociology most of its terminology (the word sociology is attributed to Auguste Comte), advanced the theory of supraorganic evolution before Darwin's *Origin of Species* appeared in 1859, and attempted a comprehensive classification of societies according to their social structures. Morgan too produced a developmental theory of cultural evolution through three "ethnical periods"—savagery, barbarism, and civilization. Maine followed the same line of inquiry in respect to legal and political institutions and Bachofen did similar work on kinship systems, attempting in particular to establish that matriarchy was an earlier evolutionary form than patriarchy.

These advances in the social sciences, though the basis for specialization in ethnology, physical anthropology, comparative sociology, etc., also linked the social sciences to geology, paleontology, and biology. In other words they linked history to natural history to yield a scientific account of the vast sweep of human fortune since the first appearance of man. There is no more exciting reading in all the literature of the social sciences than the modern summary of this branch of knowledge which is to be found in the writings of V. Gordon Childe (*Man Makes Himself* [1936], *Social Evolution* [1951]). These integrative developments were further stimulated by Darwin who had himself been influenced in his thinking about natural selection by the previous work of social scientists and particularly by Thomas Malthus' *Essay on the Principle of Population* (1798). Thus sociology and social anthropology became recognized and, under the banner of the great synthesizing idea of evolutionism, respected as worthy to march in intellectual company with economics.

There were also other movements toward a synthesis of the social sciences in the 19th century, including earlier the positivism of Auguste Comte and later the elaborate conceptualizations of German sociology. But the most powerful of these, and itself much influenced by classical economics and evolutionary theory, was Marxism. If biological and cultural evolution explained the development of nature and the primitive history of man, Marx seemed to offer the laws of motion governing not only the past but also the future of civilized societies.

Thus, by the beginning of the 20th century the social sciences gave promise of following quickly on the heels of the biological sciences into scientific maturity and academic acceptance. True, the basis for existing generalizations was being challenged and especially the theories of progress and unilinear evolution. But there was widespread optimism that the emerging specialties, or specialisms, would provide evidence for a more soundly based general sociology, the role of which in the 20th century would be to correct the bias of each particular discipline and relate it to the general body of theory. Meanwhile the universities were opening their doors to the scientific newcomers. Political economy had gained recognition in all the major countries by 1830. Edward Tylor was appointed as an anthropologist at Oxford in 1884. The University of Chicago recognized sociology from its foundation in 1890, and all of the social sciences were to be studied at the London School of Economics and Political Science founded in 1895. In Germany in 1897, Max Weber went to teach at Heidelberg and, in France, Émile Durkheim held a chair of education at the Sorbonne from 1902.

20th-Century Developments.—If the outcome in the 20th century has fallen short of Victorian hopes, and certainly the continued advance in the power of natural science with its unending implications for social, economic, and political change has lent urgency to the challenge faced by the social sciences, the advance of the sciences of man nonetheless has been considerable. The grand theoretical structures of 19th-century evolutionism, Marxism, and Comtean sociology have not survived. But four modest plants of 19th century origin were established in sturdy growth.

First may be cited a tendency for high standards of empirical method to spread throughout the specialisms in alliance with modest theory (sometimes called middle-range). The revolt against overambitious theorizing may be seen, for example, in the anti-evolutionary movement championed by the Polish-born British anthropologist Bronislaw Malinowski and by such men as Franz Boas in the United States. The subsequent trend in anthropology toward the detailed study of particular societies and communities within complex societies, using meticulous methods of observation and recording, has produced numerous examples of empiricism at its best. Social surveys in the 20th century have amassed great quantities of carefully collected data on the social structure of urban industrial societies while political science has built up a store of precise knowledge on voting behaviour, political parties, pressure groups, and the social composition of political elites, against which may be tested new theories of political behaviour.

Perhaps the greatest benefit of this period of concentration on more modest and detailed work was that the old and still valid problems of economic growth and social development could be approached anew after World War II. The urge toward improved standards of life through the spread of industrialism over the "underdeveloped" areas of the world stimulated renewed search for theories of political, social, and economic development adequate to encompass the accumulated body of fact. The problem of economic growth loomed large in postwar economic writing as may be seen from such examples as W. Arthur Lewis' *Theory of Economic Growth* (1955), W. W. Rostow's *The Stages of Economic Growth* (1960), or Simon Kuznets' *Six Lectures on Economic Growth* (1959).

This substantive concern with industrialization and social and political development has had integrating effects in the social sciences in that no one specialism is adequate to tackle the problems involved. The consequent tendency to a breakdown of specialist boundaries has involved the second trend which has been characteristic of the 20th century, namely the spread of a sociological approach into the various specialisms; *i.e.*, the recognition of the interdependence of the social, political, and economic forces which determine behaviour. Historical studies have also been affected by this development. Thus Richard Hofstadter's *The Age of Reform* (1955) is an example of a sociological orientation in history, and Neil Smelser's *Social Change in the Industrial Revolution* (1959) is a direct application of sociological theory to the Lancashire cotton industry between 1770 and 1840. Similarly, books like David Apter's *The Gold Coast in Transition* (1955) illustrate the use of sociological theory in the analysis of political change. It is from the interpenetration of the established disciplines that a new synthesis of theory is looked for and, indeed, at least one 20th-century attempt to build a unifying conceptual framework for sociology, anthropology, and social psychology has appeared in the writings of Talcott Parsons (*The Structure of Social Action* [1937; 2nd ed. 1958], *The Social System* [1951]).

The third noteworthy development has been the rise of several branches of psychology having relevance for the analysis of social behaviour. Among the more important of these are psychoanalysis, behaviourism, Gestalt theory, and the study of individual differences. Above all the influence of Freud on the social thought of the 20th century is comparable only with that of Marx and Darwin in the 19th century. Quite apart from his voluminous clinical writings Freud made direct excursions into anthropology (*Totem and Taboo* [1918]) and social psychology (*Group Psychology and the Analysis of the Ego* [1921], *Civilization and Its Discontents* [1930]). But no branch of the social sciences has escaped the influence of psychoanalytical ideas. They were introduced into political science by Harold Lasswell in his *Psychopathology and Politics* (1930) in a way which gave fresh impetus to the neglected insistence by earlier writers like Graham Wallas (*Human Nature in Politics* [1908]), Arthur F. Bentley (*The Process of Government* [1908]), and Charles Merriam (*New Aspects of Politics* [1925]) on the relevance of psychological and sociological factors in the study of political man. Psychoanalytical ideas were carried further into social anthropology by Abram Kardiner and into sociology by Talcott Parsons.

Movements in psychology other than those inspired by Freud and his earlier associates have made contributions both to theory and more especially to rigorous methods of experiment, testing, and measurement. Examples include the contribution of Clark

Hull to learning theory (*A Behavior System* [1952]), Wolfgang Köhler's work on perception (*Gestalt Psychology: an Introduction to New Concepts in Modern Psychology* [1947]). Kurt Lewin's influential *Field Theory in Social Science* (1951), and Donald Hebb's integration of Gestalt theory with neurophysiology in his *Organization of Behavior* (1949). Out of these movements there has also developed a recognized specialism of social psychology concerned with such topics as the scientific study of attitudes, public opinion, the social determinants of perception and motivation, and the interaction processes of small groups; and each of these topics boasts a considerable literature.

The fourth line of advance in 20th-century social science has been the steady improvement and extension of quantitative methods. At the end of the 19th century mathematical and statistical techniques for social analysis were in their infancy. Simple quantification had always been part and parcel of demography and the political arithmetic tradition. But, at least until after World War I, mathematical economics was not taken seriously in the English-speaking world, being largely confined to France, Italy, and Switzerland and such men as Léon Walras, Augustin Cournot, and Vilfredo Pareto. Thus the first systematic exposition of economic theory in mathematical terms, Walras' *Éléments d'économie politique pure* (1874–77), was not available in English until 1954. However, during the course of the 20th century mathematical treatments have tended to displace literary discussion, and statistical techniques have generated a new discipline of econometrics and transformed research in economics, sociology, and political science. Sampling procedures based on probability theory were introduced between World Wars I and II to make social surveys, public opinion polls, and electoral studies both economical and reliable. Psychological research has developed refined methods of factor and multivariate analysis, tests of ability and aptitude, and assessments of the significance of differences in the distribution of attributes between groups. Advances in computer technology have also revolutionized the possibilities of complex large-scale analysis of social phenomena.

SOCIAL SECURITY, a term that originated in the United States and came into common use throughout the world in the first half of the 20th century to denote programs established by law to provide for the economic security and social welfare of the individual and his family. Social security systems vary from country to country but in general they provide for benefits to the aged, widows and young children, the disabled, the unemployed, and for some form of medical care. The three principal means of providing such benefits are by social insurance, public assistance, or public service. Social insurance, as the name implies, is based on insurance principles, although other elements such as the number of dependents may also be taken into consideration. It is usually financed through contributions made to a special fund by employees and employers (and in some cases, government); the benefits depend upon the individual's earnings or contributions and are described in the statute establishing the system. Public assistance programs provide cash payments and services to needy individuals (such as widows with dependent children) to help them meet their basic needs. Under public service programs, cash payments or services are provided directly by the government to every member of the community who qualifies, regardless of his economic need or his contribution to an insurance fund.

Origin and Growth.—In most countries, until late in the 19th century, the relief of poverty was left to private charity, to churches, to workingmen's provident associations, or to the government acting under so-called poor laws (*see* POOR LAW). In 1883–84 Germany, under the leadership of Bismarck, became the first European country to introduce a modern form of social security—a contributory health insurance program (at that time called "sickness insurance"), a national compulsory accident insurance program and old-age pensions. Germany's example was soon followed by Austria and Hungary and by the early years of the 20th century public opinion in most European countries had come to favour some means of providing old-age pensions for the needy and of dealing with such contingencies as sickness and unemployment among workers. Great Britain in 1908 established a system to provide noncontributory pensions to needy persons who had reached the age of 70, and in 1911 it became the first country to adopt a national system of unemployment insurance (*q.v.*). The compulsory health insurance program adopted in Great Britain in 1911 was greatly extended in 1920. A system of contributory old-age, widows', and orphans' pensions began in Great Britain in 1925 and unemployment insurance was put on a new basis by the Unemployment Assistance Act of 1934, which set up at the same time a national system of unemployment assistance. (For the first U.S. Social Security Act, see *United States*, below.)

In no country does social insurance cover all needs and all contingencies; public assistance is therefore provided to aid those persons in need who are not entitled to some form of insurance benefit (or to supplement an insurance benefit). Whereas social insurance implies that benefit payments are made to contributors according to a formula stated in the insurance law, public assistance payments are based on a minimum level of subsistence. Public assistance as the sole or main form of social security is now used in only a few countries and is gradually being replaced by social insurance.

Social insurance programs are usually compulsory in the sense that specified categories of employers and employees are required by law to participate by paying contributions. But in some countries the system has voluntary or quasi-voluntary features.

After World War II a great deal of attention was given to social security in most European countries and in other parts of the world as well. Each year after 1945 saw the introduction of social security measures into some countries for the first time; by the mid-1960s they were in operation in more than 100 countries.

UNITED STATES

The development of social security legislation in the United States was slow, and the recognition of social welfare as a governmental responsibility was late in developing. Because an agricultural economy set the pattern of life in the 19th and early 20th centuries (except in larger towns and cities) there was little unemployment in the modern sense of that term, and family groups assumed responsibility for their members who were in need. The 19th century was characterized by a generally accepted belief that personal initiative and industry were all that was necessary for the achievement of material success. This attitude tended to support the traditional belief that indigence was synonymous with incompetence; there was a definite stigma attached to any governmental aid given the financially unfortunate. The traditional concept that public welfare was a function of local rather than state or federal government also tended to retard improvements in welfare programs. Only gradually, as welfare needs increased, did the states come to recognize that they would have to assume at least some of the burden of caring for the poor. In the first three decades of the 20th century many states made arrangements for granting public assistance to certain categories of the population, but this type of assistance was extremely limited in its coverage. Workmen's compensation (*q.v.*), which had its beginning in 1908 was the first type of social insurance to be developed in the United States, and, with the single exception of an unemployment insurance bill passed by Wisconsin in 1932, it was the only form of

social insurance in effect in the United States in 1935 when a broad national program was recommended.

Establishment of a Federal Program.—The national system of social security established by the Social Security Act of 1935 was part of Pres. Franklin D. Roosevelt's "New Deal." It provided for a system of federal old-age benefits for workers; a federal-state system of unemployment insurance; and federal financial aid to the states to help them provide public assistance to dependent children, the needy aged, and the needy blind. These programs were administered at the federal level by a bipartisan Social Security Board of three members. The other programs included in the act—provision for maternal and child health services, services for crippled children, child welfare services, vocational rehabilitation, and assistance to the states for public health—were administered by other federal agencies.

In 1939 the Federal Security Agency was created and six organizations were placed under its jurisdiction—the Social Security Board, the Public Health Service, the Office of Education, U.S. Employment Service, the Civilian Conservation Corps, and the National Youth Administration. In 1940 the Food and Drug Administration was transferred to this agency. During the next dozen years there were numerous administrative changes, followed by the creation in 1953 of the Department of Health, Education and Welfare, headed by a secretary who is a member of the president's cabinet. The Federal Security Agency was abolished and all its functions were transferred to the new department.

Old-Age, Survivors and Disability Insurance.—The old-age insurance program established by the original Social Security Act was designed to provide a basic retirement income at age 65 for workers insured under the system. Before 1935 various retirement plans had been established for public employees and private pension plans had been set up by some business organizations. But by 1930 the number of employees covered by such private plans was only about 3,500,000. The Social Security Act of 1935 provided old-age insurance for millions of additional workers, and later amendments brought in millions more. The original act covered only employees in industry and commerce—about six out of ten workers in the labour force—for old-age benefits. Thirty years later the law provided almost every wage earner, salary earner, and self-employed person with social insurance protection against three basic risks—old-age, long-term disability, and death of a breadwinner.

Coverage.—Chiefly because of the administrative difficulties involved, certain types of employment were not at first covered by the Social Security Act. Among the types of work not covered were agricultural labour; domestic service; casual labour not in the course of the employer's trade or business; service as an officer or member of the crew of a merchant ship; employment with any federal, state, or local government or its instrumentality; and service with certain religious, charitable, humane, and educational institutions not operated for profit. Railroad employment was excepted because it was covered by a separate system established by the Railroad Retirement Act. All employment after age 65 was also excepted.

Under the 1939 amendments some of the types of employment previously excepted were brought under the system. These included service on U.S. vessels and employment in national banks, building and loan associations, and certain similar organizations. The exclusion of employment after the age of 65 was removed as of Jan. 1, 1939, thus enabling many workers previously ineligible because of age to qualify for benefits and enabling others to increase the amount of their benefits. At the same time, the amendments added certain exceptions. The term "agricultural labour" was redefined to exempt some services that were closely related to farming. Certain part-time or intermittent employment providing only nominal wages, services of newsboys under 18 years of age, family employment, and employment for foreign governments were also excluded by the 1939 amendments.

Under the 1950 amendments, coverage was broadened to include the self-employed (except farmers and those in certain professions) and regularly employed agricultural and domestic workers. Voluntary coverage was permitted for employees of nonprofit institutions and of state and local governments not already under a retirement system. Certain civilian employees of the federal government not under a retirement system were also included. Amendments in 1954 extended coverage to about 10,000,000 additional workers, most of whom were self-employed farm operators. Coverage was given to additional members of state and local government retirement systems, and to larger numbers of agricultural and domestic workers by liberalizing the definition of the term "regular employment." In 1956, coverage was extended to several additional groups of the self-employed. Larger numbers of farm owners and operators were brought within the coverage of the act, and, except for doctors of medicine, most self-employed professional people were included. Coverage was also extended to almost 3,000,000 members of the uniformed military services on active duty. In 1965 self-employed physicians were covered and the only large group outside the system were the civilian employees of the federal government who were covered by other federal systems.

Contributions (Taxes).—In the beginning, old-age and survivors insurance was financed solely by a payroll tax levied on both employees and employers. The tax rate was 1% per year on the first $3,000 of the wages of each employee, matched by the same amount paid by the employer. An increase of ½% was to be made every three years until in 1949 a total contribution of 6% would be payable (3% by employers and 3% by employees). The 1939 amendments, however, eliminated the ½% increase for the years 1940–42, and, because of subsequent acts of Congress, the tax did not actually increase to 1½% until Jan. 1, 1950.

Under the 1950 amendments the 1½% rate of tax was retained for 3 more years, and the tax for the newly covered self-employed persons was set at 2¼% of net earnings. At the same time a new maximum earnings base of $3,600 was established. In 1954 the combined employer-employee tax rate was 4% (2% each) while each self-employed person contributed 3%. The same rates were retained for 1955–56 but the maximum taxable earnings base was increased to $4,200. In 1957 the schedule of rates was increased by ¼% to cover the cost of disability insurance benefits, with the combined employee-employer rate a total of 4½% of the earnings base while the self-employed began paying 3⅜%. Scheduled increases in 1959, 1960, 1962, and 1963 brought the contribution rate for 1965 up to 7¼% for employees and employers (3⅝% each) and 5⅜% for the self-employed. The tax was then paid on the first $4,800 of earnings. The 1965 amendments increased benefits, adjusted the contribution schedule, and increased the maximum earnings base to $6,600 beginning in 1966. The 1966 rate was established at 7.7% for employers and employees (3.85% each) and 5.8% for the self-employed. The schedule provided increases in steps until the tax would reach 9.7% (4.85% each) and 7% respectively in 1973. The law provided for additional contributions for hospital insurance beginning at $\frac{7}{10}$ of 1% in 1966 ($\frac{35}{100}$% each) and reaching by progressive steps 1.6% in 1987 ($\frac{8}{10}$% each).

Financing.—Under the act of 1935 an old-age reserve account was established in the United States treasury wherein receipts from the payroll taxes were to be deposited, with future benefit payments to be made from this account without drawing on the general revenues of the government. The act specified that reserve funds in the account were to be invested in government obligations or government-guaranteed obligations bearing 3% interest. Although the amendments adopted in 1939 temporarily increased the costs, Congress, as noted above, held the contribution rate at 1% until 1950. In spite of this, the trust fund grew more rapidly than had been expected, partly because of high wartime employment and earnings, and partly because of increased employment opportunities for older workers during the war years. Between 1950 and 1956 there were three changes in the benefit formula; one nearly doubled the benefits while the other two provided for more moderate increases. Although individual benefits increased substantially and contributions remained at 1½% until 1954, when they were raised to 2%, the total assets in the fund continued to increase. In 1957 a separate disability insurance trust fund was established to provide payments to persons who became totally disabled. Increased costs of the program were

accompanied by increases in the contribution rates every year or two.

As a result, the program was fully supported by the social security taxes paid by workers and their employers without any general subsidy. For a time during the 1940s the law had included authorization to appropriate from general revenues any additional money that might be needed to finance the benefits, but additional money was not needed. In 1950 Congress made clear its intention that social security taxes, plus the interest earned on accumulated funds, should be sufficient to meet all of the costs of the program without any subsidy from general revenues.

Benefits.—The 1935 act provided for the payment of monthly benefits, beginning in 1942, to insured workers who were 65 years of age or over when they retired. Benefits were to be based on the employee's total wages during the qualifying period (exclusive of amounts received in excess of $3,000 per year from any one employer). The formula used to compute benefits was weighted somewhat in favour of the lower-paid worker. The maximum monthly benefit was set at $85, the minimum at $10. A lump-sum payment equal to 3½% of the employee's total wages was provided for those reaching age 65 without qualifying for monthly benefits; and a death benefit of the same amount was provided subject to deduction of any benefits the worker might have received during his lifetime.

The 1939 amendments made material changes in these benefits by advancing the start of monthly benefit payments to 1940 instead of 1942, increasing benefit rates, and bringing greater security to the family group by providing benefits to certain dependents and survivors of insured workers. Because of this latter extension of the system, the title was changed to "old-age and survivors insurance," abbreviated as OASI. Instead of computing the benefit rate on the basis of total wages received, a new formula based on average monthly earnings was adopted.

From 1939 through 1950 the average monthly wage was determined by dividing a worker's total wages, exclusive of annual amounts in excess of $3,000, by the number of months he could have worked under the system; *i.e.*, the number of months after 1936 (or his 22nd birthday, if later) and the date of retirement or death. In 1950 the benefit formula was amended to make it possible, beginning in 1951, to include in the computation earnings up to $3,600, and to use only those earnings credited after 1950, if this would yield a higher benefit rate. One reason for this "new start" was that the amendments of that year brought in many new groups who had no earnings to their credit for the earlier period. In 1955 the maximum earnings taken into account in computing benefits was increased to $4,200 a year, in 1959 to $4,800, and in 1966 to $6,600.

In addition to increasing the maximum earnings on which benefits were based, the formula for determining benefits was several times revised to provide larger payments. Between 1940 and 1950 benefits were related not only to wages but also to years under the system; for each year of coverage an increment of 1% was added. A worker with an average monthly wage of $200 in the 1940–1950 period would have been entitled to a benefit of $41.50 per month if his association with the system had been limited to three years. However, if he had been in covered employment for the entire period his monthly benefit would have been $45.20. Beginning in 1951, the benefits rates were increased, but the 1% increment for each year of coverage no longer applied. A person with average earnings of $250 a month, provided he met other conditions of entitlement, would have received $72.50 per month and if his earnings were $300 per month (the maximum then creditable) his monthly benefit would have been $80. The 1958 act provided $95 a month for the worker with average annual earnings of $3,000 (equivalent to the former $250 per month) and $127 a month for the worker with the maximum creditable average annual earnings of $4,800. The 1965 amendments increased benefits 7% retroactive to Jan. 1, 1965. Minimum benefits were increased from $40 to $44 a month. An increase in the contribution and benefit base to $6,600 a year made possible a maximum monthly benefit of $168. Average old-age benefits were $23 a month in 1940, $44 in 1950, and $84 in 1965.

As originally passed, the Social Security Act provided benefits only for insured persons. As noted above, the 1939 amendments made supplementary benefits available for certain family members of a retured worker and certain survivors of a deceased insured person. Beginning in 1940, benefits equal to one-half the worker's benefit were paid to a wife 65 years of age and older and also to each unmarried dependent child under 16 years of age (or under 18 if regularly attending school). In case of the death of an insured person, three-quarters of the insured's earned benefit would be paid to his widow if she was 65 years of age or over, or to his widow, regardless of age, if she had dependent children. Benefits equal to one-half the worker's benefit would be paid to each of these dependent children and, if there were no other family members eligible for benefits, to dependent parents. With the 1950 amendments, the wife of a retired worker, regardless of her age, was entitled to benefits if she had in her care a child of his who was eligible for monthly benefits. For the first time benefits were payable to a dependent husband (age 65 or over) of a retired or deceased woman worker. Benefits for the first surviving child were raised to 75% of the insured person's benefit. The 1960 act extended this percentage rate to all children, while legislation in 1961 increased the aged widow's or widower's rate to 82½% of the basic rate, which also applied to a dependent parent (75% for each if there were two such parents). Total family benefits were subject to statutory maximums, with the 1958 act setting up the maximum monthly figure of $254 or 80% of the average wage whichever is smaller, but in no case less than 1½ times the worker's basic benefit. The 1965 amendments modified the method of computing the family maximum and raised the monthly maximum to $368 for a family.

Under the 1956 amendments women became eligible to draw benefits at age 62, reduced on an actuarial basis for each month before age 65 if they claimed benefits as wives of retired workers—or without a reduction if they were widows. The 1961 amendments extended a similar provision to men. The amount of reduction was adjusted for persons who retired at any time between age 62 and 65. The 1965 amendments permitted a widow at age 60 to elect a benefit actuarially reduced for each month she is under age 62.

To make the social security system one that would more nearly provide lifetime social insurance protection for insured workers their dependents, and their survivors, the beginnings of a disability insurance program were included in the 1954 amendments. This provided for a "freezing" of the worker's old-age and survivors account at the beginning of the year prior to his becoming totally disabled. This was somewhat analogous to the "waiver of premiums" feature of commercial insurance programs. The period of disability was to be disregarded in determining the amount of eventual benefits. The 1956 amendments provided for payments to disabled individuals who had reached age 50, and to dependent sons and daughters of retired and deceased workers, if the child's disability began before age 18. The 1960 law removed the age qualification for entitlement to disability insurance benefits. The benefits payable to a disabled worker and his dependents were made the same as if the worker had attained age 65 at the time he became disabled. In 1965 further changes were made in the disability insurance benefit including liberalization of the definition of disability and inclusion of reimbursement from social security funds for the rehabilitation of disabled persons.

In addition to the periodic benefits, a lump-sum payment was made available on the death of the insured worker. From 1940 through 1950 these payments were made (if no monthly survivor benefits were payable) to relatives or to the person who paid the funeral expenses. The amount of the payment so made was then six times the worker's monthly benefit rate. After 1950, an amount equal to three times the worker's monthly benefit rate was made to the spouse, if one survived, or to the person paying the funeral expenses. Under the 1939 act the maximum lump-sum death benefit was $360 (assuming 50 years' coverage). The 1950 amendments set a maximum of $240, and the 1954 act increased this to $255.

Eligibility for Benefits.—To qualify for benefits, a person must

have had earnings in covered work over a specified length of time, which may vary with the individual's date of birth, sex, and the type of benefit that is being applied for. Since 1939 the act has provided for two kinds of insured status—"fully insured" and "currently insured." The 1939 act required that a worker was not fully insured until he had received at least $50 in covered employment in each of 40 calendar quarters or in each of enough calendar quarters to equal half the calendar quarters elapsing between Dec. 31, 1936 (or his attainment of age 21, if later) and the quarter in which he died or attained the age of 65, but never any fewer than six calendar quarters. The method of determining eligibility on the basis of calendar-quarter credits was modified somewhat by later amendments. This was necessary because new groups were brought under the act and because self-employment income was not credited until after 1950. After 1950, most self-employment net earnings of at least $400 in a taxable year yielded four quarters of coverage. Under the 1961 act persons were considered fully insured if they had quarter-of-coverage credits equal to at least the number of years after 1950 (or after age 21, if later) and up to age 65 (62 for a woman), or up to the date of death, if this occurs earlier.

If a worker dies before acquiring "fully insured" status, certain survivors benefits may be paid if he is "currently insured," *i.e.*, if he had credit for at least a year and a half of covered work within the three-year period prior to his death. For a dependent husband or widower to be eligible for benefits from the work of a woman worker, she must have been both fully and currently insured at the time of her death, attainment of age 62, date of disability, or the time of filing of her application for old-age benefits, if after age 62. Generally speaking, an applicant for disability insurance benefits, in addition to having "fully insured" status as of the date of disability, must also have credit for covered work in 5 out of the 10 years ending when he became disabled.

Once benefits have started, certain events can cause them to be suspended for one or more months or be terminated altogether. Under the 1935 act, retirement was required for receipt of old-age benefits—receipt of any earnings in covered employment was sufficient cause to suspend benefits for the month or months in which they were earned. The 1939 act modified the retirement requirement and allowed benefits to continue if earnings in covered employment were less than $15 a month. In 1950 the act was amended to provide that benefits would be paid to persons age 75 and over, irrespective of retirement, and for those under age 75 benefits could be paid if covered earnings did not exceed $50 a month, and this figure was increased to $75 by the 1952 amendments. The 1954 amendments allowed all benefits to be paid during a year when earnings did not exceed $1,200 (including all earnings whether in covered employment or not). Beginning in 1966 a beneficiary could earn up to $1,500 a year in any employment without loss of benefits. For each $2 of the next $1,200 of earnings, $1 of benefits was withheld, and for each $1 of earnings over $2,700, $1 was withheld. For beneficiaries age 72 or over there was no retirement requirement. Some other events that may terminate benefits are remarriage on the part of a widow, divorce of a wife, adoption by a person outside the family, marriage of a child receiving benefits, or recovery of health or demonstration of ability to work on the part of a disability beneficiary.

Unemployment Insurance.—The provisions of the 1935 Social Security Act relating to unemployment insurance were designed to stimulate adoption of state systems that would insure employees against total loss of income during periods of unavoidable unemployment. Because of constitutional law problems, this approach was considered preferable to a wholly federal system of unemployment insurance. Unemployment insurance bills had been presented in a number of state legislatures before Congress considered the Social Security bill in 1935. The burden that such legislation would place on state industries in competition with industries in states without such legislation had deterred action in all states except Wisconsin. By levying a federal tax on employers and then allowing credit against this tax for contributions made to a state unemployment fund, the federal act helped to remove the interstate competitive factor, and by June 30, 1937, all states had enacted unemployment insurance laws. Under the terms of the federal act, wide latitude was allowed the states in adopting unemployment insurance systems, but the state laws nevertheless had many basic similarities.

Financing.—The unemployment insurance provisions of the Social Security Act levied a federal payroll tax on employers who had eight or more employees, certain types of employment excepted. The rate of this tax was set at 1% of wages up to $3,000 per year in 1936, 2% in 1937, 3% from 1938 to 1961 and $3\frac{1}{10}$% in 1961 and thereafter. Federal legislation in 1954 required employers of four or more employees to pay this tax beginning in January 1956. Against this federal tax, employers were allowed credit for the amounts they contributed to unemployment insurance funds under a state law approved by the Social Security Board. The maximum credit allowed was 90% of the 2.7% federal tax, thus providing funds for the federal government to meet necessary administrative costs. The federal law allowed an employer credit for any reductions in his state rate of contribution resulting from favourable experience in regard to payment of unemployment benefits. As a result of the experience-rating provisions, the average employer contribution to state unemployment insurance funds was 2% of taxable payroll. The employer's contribution, like the federal tax, was ordinarily based on the first $3,000 of earnings. By the 1960s, however, several states had raised the taxable wage base to $3,600 or more. Employee contributions were required by only a few states.

All money collected by the states for unemployment insurance is deposited in the U.S. treasury in an unemployment trust fund to be drawn upon by the states to pay benefits. Until 1954 the unemployment tax paid to the federal government became part of the revenue of the federal treasury, and funds necessary for administration were appropriated annually. Unemployment tax collections consistently exceeded these appropriations, and thus parts of the tax funds were not used for the employment security program. A 1954 amendment earmarked these taxes collected in excess of administrative expenses, and the funds became available for noninterest-bearing loans to states whose funds fell below a specified level. This amendment substantially increased a continuing ability to pay benefits in states with relatively high levels of unemployment.

Coverage.—The 1935 federal law excepted from the employer's tax wages paid for the following services: agricultural labour; domestic service; shipping on navigable waters of the United States; employment for the immediate family; federal, state, and local government service; and employment by certain religious, charitable, and educational organizations not organized or operated for profit. Railroad employment was exempted from coverage when the federal Railroad Unemployment Insurance Act was enacted in 1938.

The amendments of 1939 extended coverage of the federal unemployment insurance tax to wages paid for employment by national banks, building and loan associations, and similar organizations, and in 1946 maritime employment was added. In 1954 a federal employment insurance law provided compensation to federal employees for income lost because of unemployment. Most state laws closely followed the occupational exclusions of the federal unemployment tax act. By the mid-1960s workers covered by unemployment insurance represented about 60% of the labour force and 80% of all civilians earning wages or salaries.

Benefits.—From the beginning, all state laws provided that weekly benefits be related to the weekly wage of the individual worker. In 1939 average benefits in the country as a whole were about 40% of the average wage of covered workers, and although benefits increased substantially thereafter, the increases lagged behind rising wages. Thus, by the mid-1960s the average benefit had dropped to less than half the weekly wage.

Both the amount of the benefit and the length of time for which it could be paid have differed from state to state and from year to year. By 1964 average weekly benefits for the United States as a whole were $36. Maximum weekly benefits varied widely from state to state. Unemployment insurance in the United States was designed to cover only relatively short periods of unemploy-

ment. In the early years of this legislation most laws provided benefits for a maximum of 16 weeks. By the mid-1960s practically all states set the maximum at 26 weeks and about a fifth of all states had a maximum exceeding 26 weeks. In virtually all states a waiting period of one week was required before benefits became payable. In 1958 and again in 1961 the federal government provided for a temporary extension of unemployment compensation for workers who had exhausted their regular state benefits. All the state laws denied benefits to claimants who were unavailable for work or were unable to work; were involved in a labour dispute; voluntarily left their jobs or refused work without good cause; or were discharged for misconduct. When a worker applied for unemployment benefits he registered at a state employment office, reported to that office each week as evidence that he was able and willing to work, and was obliged to accept any "suitable" employment (as defined by the state) offered him.

Public Assistance.—The act of 1935 made provision for granting federal funds to the states to aid them in giving financial assistance to three groups of needy persons—the aged, the blind, and dependent children. In contrast to social insurance benefits, which are available to all persons who qualify as to age, disability, or inability to find a job and who meet the requirements as to length of time in covered employment, public assistance is available only after proof of need—a so-called means test. The states adopt and administer their own public-assistance plans, but each state plan must be submitted to the federal government for approval. Standards for approval of state plans specified by the Social Security Act of 1935 were designed to assure efficient administration and equitable distribution of assistance. Each state, however, was free to determine the amount of the assistance grant and its own eligibility conditions so long as such provisions were not more restrictive than those required for approval by the federal act. The state laws thus differed considerably, some being distinctly more liberal than others.

The 1935 act fixed the amount of federal funds available to the states for old-age assistance and aid to the blind at one-half the state's total assistance payments, up to a monthly federal-state maximum of $30 to each recipient. For aid to dependent children, the act provided federal grants equal to one-third of the amount paid by the state. As a basis for computing the federal share of aid, the act set a maximum of $18 a month for the first child and $12 for each additional child in the same home. A dependent child was defined as one who is under age 18 (until 1956 children between the ages of 16 and 18 had to be regularly attending school), is without parental support because of the death, disability, or continued absence of a parent (or because of unemployment of a parent after the 1961 amendments), and who is living in his own home or with certain near relatives (or receiving foster care under conditions specified in the 1961 and 1962 amendments). The federal government also made grants to the states that covered one-half the cost of administration. In 1962, in order to encourage the states to expand their social services for the rehabilitation of needy persons, the federal share of providing social services under the state plans was increased from one-half to three-quarters of the cost. After 1935 the federal grants to states for public assistance were increased several times, and in 1950 these grants also became available for aid to the needy who are permanently and totally disabled. In 1960 grants were made available for medical assistance for aged individuals needing help only in meeting their medical expenses. The 1965 amendments added two health insurance programs for the aged (*see* below) and also extensively revised the medical assistance program and broadened it to enable the federal government to help finance state payments for medical services for practically all needy persons. By the mid-1960s medical assistance had become a substantial and still growing part of the public assistance program. As with cash payments, the medical assistance provisions of state programs varied widely with respect to groups covered, income and other eligibility conditions, and the scope of medical services covered. As a result of legislation during the early 1960s, federal funds were made available to states and localities for work relief and training programs for needy persons on public assistance.

Health and Welfare Services.—The original Social Security Act, in addition to its provisions for social insurance and public assistance, included federal grants to help states develop maternal and child health services, services for crippled children, and child welfare services. At the federal level, the state programs were administered by the Children's Bureau of the Welfare Administration. The sums granted by the federal government for these services were increased several times over the years and on various occasions, funds were earmarked for specific problems such as maternity and infant care, for the health of school and preschool children, and to provide day care for children of working mothers. The act of 1935 also provided funds for distribution to the states to assist them in extending public health services. The approval of the surgeon general of the United States was required for all state programs, and the federal Public Health Service assisted the states in improving their work in this area. As a result of separate legislation grants were made for general public health, to aid in the control of tuberculosis, cancer, venereal disease, mental illness, heart disease, for the health of migrant workers and those chronically ill and aged, and for construction of hospitals and community mental health centres. In 1963 and 1965 grants were also made under the Social Security Act to combat mental retardation.

Federal grants to states for vocational rehabilitation were made as early as the 1920s. The Social Security Act of 1935 continued this program and increased the grants. Separate legislation in 1943, 1954, and 1965 expanded the program. The purpose of such legislation was to assist the states in providing disabled persons with services that would enable them to engage in remunerative employment. Any person who had a physical or mental disability and could reasonably be expected to become employable was eligible to participate in the program.

Workmen's Compensation.—It was not until about 1900 that the tremendous losses due to industrial accidents in the United States gained recognition and the movement for workmen's compensation got under way. Before enactment of workmen's compensation laws, an injured worker who sued his employer for compensation had to prove that the employer had been negligent. The employer was also entitled to various specific defenses under the common law, and the court procedure was slow, costly, and uncertain. Workmen's compensation legislation introduced a new legal and economic principle. the concept of individual fault was abandoned, and the cost of industrial injuries was considered to be part of the cost of production. (*See* WORKMEN'S COMPENSATION.)

Social Insurance for Special Groups.—Retirement and unemployment insurance are provided by special legislation for railroad workers. The Railroad Retirement Act of 1935, with later amendments, included the same types of benefits provided under federal old-age and survivors insurance, but higher contributions were required and the benefits, in most cases, were more liberal for railroad workers. A federal railroad unemployment insurance law was passed in 1938, and after 1946 this legislation also included temporary disability benefits. These benefits were financed initially by a tax on employers fixed at 3% of the first $300 of monthly wages. After 1948, however, because of high employment and a large reserve, employers were permitted to pay a tax much lower than 3%, the actual tax for some years being only ½% of wages. In 1964 the rate was 4% on the first $400 of monthly wages. This act was similar in many respects to the general state unemployment insurance acts. The average benefits, however, were higher (about $50 a week in the early 1960s in contrast with an average benefit paid under the state laws of about $35). Another difference between this federal act and the state laws was that all railroad employers paid the same tax rate, whereas the state acts allowed the individual employer's contribution to vary on the basis of the amount of unemployment of his workers.

There are many different types of retirement systems for employees of state and local governments. After 1951 it was possible for employees with no retirement systems of their own to be brought under the federal old-age and survivors insurance law on

a voluntary basis. After 1954 employees covered by a state or local retirement system could be brought under federal old-age and survivors insurance.

A federal civil service retirement system was established in 1920 and was improved and liberalized many times. The vast majority of the employees of the federal government were covered by this system. In 1950 the federal old-age and survivors insurance law was amended to cover a considerable group of federal workers (mainly temporary employees) who were not covered by the civil service retirement system. The civil service retirement system is financed by contributions of 6½% of the employee's total wage or salary. The government made no specific contribution but assumed responsibility for any deficiencies in the fund. The benefits were based on the employee's salary and length of service. They were in most cases much larger than those paid under federal old-age and survivors insurance, although civil service benefits might be lower for employees with short periods of service.

Health Insurance (Medicare).—The Social Security amendments of 1965 established two coordinated health insurance programs for the aged (65 or older) and were popularly known as "Medicare." The basic plan, which went into effect in July 1966, covered hospital and related services and was financed by increasing the social security taxes paid by employers, employees, and the self-employed. The hospital insurance taxes began at 7/10 of one percent (half paid by the employer and half by the employee) and were scheduled to reach 1.6% in 1987. The cost of benefits for those not covered by social security was met out of general revenues. The voluntary supplementary plan paid for physicians' services and was financed by a $3 monthly contribution, beginning in July 1966, by each individual 65 years of age or older and an equal contribution by the federal government from general revenues.

The basic plan provided for payment of most of the aged individual's hospital costs for up to 90 days of care for each spell of illness; the patient was required to pay the first $40 of his hospital expenses and $10 a day after the first 60 days. The plan also provided (effective in 1967) for up to 100 days of extended-care services in a nursing home (after 3 or more days of hospitalization) with the beneficiary paying $5 for each day beyond the 20th. In addition, the plan provided up to 100 health services (such as a visit by a nurse) to a patient at home following discharge from a hospital or nursing home, and outpatient hospital diagnostic services with the patient paying the first $20 and 20% of the cost of services from the same hospital during a 20-day period. Inpatient psychiatric services were covered, but with a lifetime limit of 190 days of care.

The voluntary supplementary plan was open to persons 65 or older who chose to enroll in it. It provided for paying doctor bills and related medical expenses and was administered through private insurance firms. Under this plan the patient paid $50 of his annual medical expenses and the government paid 80% of the patient's bill (above the $50) for the following services: physicians' and surgeons' services, whether furnished in a hospital, clinic, office, home, or elsewhere; home health services (with no requirement of prior hospitalization) for up to 100 visits during each calendar year; X-rays; laboratory tests; surgical dressings; wheelchairs; artificial legs, etc. Outside-the-hospital treatment of mental illness was limited during any calendar year to $250 or 50% of the expenses, whichever is smaller.

SOCIAL INSURANCE IN GREAT BRITAIN AND THE COMMONWEALTH

A comprehensive new system of social insurance in Great Britain came into operation on July 5, 1948, as a result of the report of Sir William (later Lord) Beveridge. It greatly expanded and integrated the various social insurance programs that had been adopted during the preceding 40 years. The statutes under which the various parts of the scheme were initiated were the National Insurance Act, 1946, the National Health Service Act, 1946, and the National Assistance Act, 1948. The cost was to be shared by insured persons, employers, and the state. (See *Contributions*, below.) In general, every person in Great Britain over school-leaving age and under pensionable age became insured as a member of one of the following classes: (1) employed persons; (2) self-employed persons; and (3) nonemployed persons. Married women might choose whether or not to contribute under special conditions applicable to them.

Benefits.—The rates of benefit were generally similar regardless of the basis for need (unemployment, sickness, widowhood, or old age). Under the National Insurance Act, 1964, for an adult (over the age of 18), other than a married woman, the weekly rate was £4, with an allowance for one child of *22s. 6d.*, 14*s.* 6*d.* for each additional child and 50*s.* for an adult dependent. The benefits for children were in addition to the family allowance payable for other than the first child. A married woman over 18 received 55*s.* unless she was supporting an invalid husband or not residing with and unable to obtain any financial assistance from her husband, when she was paid the full £4 rate. Boys and girls under 18 without dependents received 45*s.* 6*d.*

Unemployment Benefit.—To qualify for unemployment benefit a person had to be available for employment and to have paid at least 26 contributions. The standard rate of benefit was payable during a benefit year if in the previous contribution year 50 contributions had been paid or credited. Unemployment benefit was payable for 180 days, plus additional days calculated on the claimant's recent record of contributions and benefit. After that he would not be entitled to further benefit until he had been back at work for 13 weeks and had paid 13 contributions.

Sickness Benefit.—To qualify for sickness benefit a person must have paid 26 contributions since entry into insurance. The standard rate of benefit was payable during a benefit year if in the previous contribution year 50 contributions had been paid or credited. If less than 50 contributions had been paid or credited, benefit was payable at a reduced rate.

Maternity Benefits.—These consisted of maternity grants and maternity allowances. A maternity grant of £22 was payable for each baby born if either the mother or her husband had paid 26 contributions before the date of confinement and had at least 26 contributions paid or credited in the last complete contribution year before the benefit year in which the confinement took place. A maternity allowance of £4 weekly was payable to an employed or self-employed woman who gave up paid work for the period for which the allowance was granted. This was normally a period of 18 weeks beginning with the 11th week before the expected week of confinement.

Widows' Benefits.—There were three kinds of widows' benefits, each being dependent upon the husband's contributions only: (1) widow's allowance; (2) widowed mother's allowance; (3) widow's pension. The widow's allowance of £5 12*s.* 6*d.* was payable for 13 weeks together with allowances for children (in addition to family allowance). The allowance was not payable if the widow was over 60 and her husband was entitled to a retirement pension, as she would then be entitled to a pension with her husband.

If the widow had a family which included a child under school-leaving age she would receive a widowed mother's allowance of £4 per week when she had finished drawing her widow's allowance, with an extra allowance for each child. In certain circumstances a widow could obtain a widow's pension at the rate of £4 a week when her other allowance ceased.

Retirement Pension.—The expression "old-age pension," for which provision was made in previous statutes, was replaced by "retirement pension." This was paid at a rate of £4 a week to an insured man aged 65 or over or to an insured woman aged 60 or over who had retired from regular employment and satisfied certain prescribed conditions.

Where a wife received a retirement pension on her husband's insurance the rate was 50*s.* An allowance of 22*s.* 6*d.* was payable to a retirement pensioner for his eldest dependent child and 14*s.* 6*d.* each for younger children.

"Retirement" as understood under the act did not necessarily mean that the person had ceased to do any paid work. He could be treated as retired although he was engaged in a gainful occupa-

tion provided that such occupation was only occasional or inconsiderable in extent or otherwise not inconsistent with retirement. The amount a retirement pensioner could earn without reduction of his pension was limited. At the age of 70 (65 for women) the full rate of retirement pension then earned would be paid though the pensioner might continue to work. There were certain advantages if a person remained at work after pensionable age. He could still obtain unemployment and sickness benefit within certain limits up to the age of 70 (65 for women) and could also earn a higher rate of pension. For every 12 contributions paid as an employed or self-employed person during the five years after reaching pension age, the retirement pension would be increased by 1*s.* a week. The rate of the wife's retirement pension would also be increased.

Death Grant.—A death grant to help meet funeral expenses was payable on the death of certain insured persons, or on the death of the wife, widow, husband, or child of their family, at a rate of £25 for an adult and smaller sums for persons under 18 years of age. Death grants were not payable for men born before July 5, 1883, or for women born before July 5, 1888, and they were payable only at a reduced rate of £12 10*s.* for men born between July 5, 1888, and July 5, 1898. The reasons for these disqualifications was that death grants had not been provided by the state insurance programs prior to July 5, 1948.

Contributions.—The weekly contribution paid by an adult employed man under the National Insurance Act, 1964 (including, provided that he was earning at least £9 a week, an additional contribution, graduated according to his earnings, entitling him to a higher flat-rate retirement pension), was 13*s.* 8*d.*; that of an adult employed woman was 11*s.* 5*d.* This contribution was reduced to 9*s.* 5*d.* for a man and 7*s.* 8*d.* for a woman earning £5 a week or less. Boys and girls under 18 years of age contributed 9*s.* and 7*s.* 6*d.* respectively. The corresponding employers' contributions were: 12*s.* 11*d.* for each man and 11*s.* 2*d.* for each woman, increased to 17*s.* 2*d.* and 14*s.* 11*d.* respectively when the employee's remuneration was £5 a week or less. Employers paid 9*s.* for boys and 7*s.* 6*d.* for girls. For self-employed persons the rates were: men, 18*s.* 8*d.*; women, 15*s.* 4*d.*; boys, 10*s.* 6*d*; girls, 9*s.* For nonemployed persons the rates were 14*s.* 11*d.* for men between 18 and 65 years of age and 11*s.* 7*d.* for women between 18 and 60 years of age; and for boys and girls under 18, 8*s.* 5*d.* and 6*s.* 10*d.*, respectively.

National Assistance.—The National Assistance Act, 1948, provided a unified national system of financial assistance according to need in place of various services provided previously by the state or local authorities. It was placed under the administration of the National Assistance Board, with offices throughout the country. It was the duty of the board to assist persons who were without resources or whose resources (including benefits receivable under the National Insurance Acts) were insufficient to meet their requirements. The question of whether a person was in need of assistance and the nature and extent of any assistance to be given were decided by a local officer of the board in conformity with general regulations made by the minister of national insurance, but provision was made for consulting a local advisory committee in special cases. The Board's officers themselves, however, used considerable discretion in applying the regulations. There was special provision for blind persons and persons who suffered a loss of income in order to undergo treatment for pulmonary tuberculosis. The cost of national assistance was met out of national taxation.

Noncontributory Old-Age Pensions.—Noncontributory old-age pensions, as distinct from contributory pensions, were payable under the Old Age Pensions Act, 1936, subject to a means test. They were a direct charge on the national exchequer and did not come out of the insurance fund. They applied to a diminishing number of old people who had not become entitled to retirement pensions by contributing under the national insurance acts. Unlike retirement pensions, which were payable at 65, a noncontributory pension was not payable until the age of 70.

Workmen's Compensation.—Provision was made under the National Insurance (Industrial Injuries) Act, 1946, for the compulsory insurance of all persons engaged in insurable employment against personal injury caused by accidents, or the contraction of certain industrial diseases arising out of or in the course of such employment. The provisions of the act therefore replaced the former provision for the payment of workmen's compensation under the various workmen's compensation acts, the first of which was passed in 1897. (*See* also WORKMEN'S COMPENSATION.)

Health Services.—Various health services without direct payment were made available to the whole population under the National Health Service Act, 1946. These included: (1) hospital and specialist services; (2) certain domiciliary services provided by local health authorities; and (3) general medical, dental, pharmaceutical, and ophthalmic services.

Everyone became entitled to free medical services and had the free choice of a medical practitioner from whom treatment might be obtained, provided the medical practitioner had agreed to serve under the program. The doctor was paid a fee for each person on his list, together with certain additional allowances. Medicine prescribed by the doctor could be obtained free from any pharmacist taking part in the service. Dental treatment, for which a fixed charge was imposed later, was also available from dentists participating in the service. Their remuneration was paid according to scales of fees for various types of work. General responsibility for the National Health Service was vested in the minister of health, who acted through regional hospital boards and hospital management committees; the domiciliary service was administered by the county and county borough councils. (*See* MEDICAL CARE, GOVERNMENT.)

National Insurance Administration and Finance.—The minister of national insurance, later designated the minister of pensions and national insurance, was made responsible for the administration of the program. His department worked through regional and local offices in close association with the local employment offices of the Ministry of Labour and National Health Service. A national insurance advisory committee was established to assist the minister in discharging his functions under the act with the special task of considering any draft regulations before their submission to Parliament. There were also local advisory committees throughout the country which assisted local officers of the ministry. Contributions were paid by the purchase of special stamps at any post office; one of these stamps was to be affixed to the insured person's contribution card for each week of employment but special arrangements could be made for stamping in bulk. When the national insurance plan came into operation the invested assets of the former health, unemployment, and pensions plans, amounting to about £900,000,000, were taken over. Of this, £100,000,000 was credited to the national insurance fund (under the control of the minister) to meet the payment of insurance benefits and the cost of administration. Into this fund was to be paid the money received from the sale of insurance stamps. The remaining £800,000,000 of the old funds was used to constitute a reserve fund. The interest on the investment of this fund was to be paid into the main fund. In addition to bearing the cost of benefits under the national insurance plan, contributions had to be made from the fund toward the cost of the National Health Service.

British Commonwealth Systems.—At mid-20th century schemes of social security were operating in most Commonwealth countries to a varying degree. In Australia there was no contributory insurance program, but social security services were provided by the Commonwealth Department of Social Services and the cost was met by the exchequer. Maternity allowances and child endowment were paid without a means test. For unemployment and sickness benefit there was a means test on income (although not on property); and for widows' pensions, old-age pensions and invalid pensions (except for blind persons) there was a means test on both property and income. In New Zealand the general social security benefits were also subject to an income test, but legislation provided for the gradual elimination of the means test for old-age pensions by the substitution of a superannuation benefit available to persons aged 65 and over who satisfied certain residential qualifications. A person in

receipt of any other benefit under the Social Security Act, 1938, except family benefit, was not entitled to superannuation benefit. The rates for this benefit (consolidated by the Superannuation Act, 1964) were £4 16*s.* weekly for a husband, the same for his wife (provided she had reached the age of 65), and £5 6*s.* for a single person.

In Canada the first social security plan, established in 1940, provided only for unemployment insurance. In 1952 a comprehensive federal scheme was introduced covering old age, disability, and workmen's compensation. Public assistance was provided by the provinces. Old-age pensions were financed through a 3% sales tax, a 3% tax on net corporation income, and subject to a maximum limit, a 4% tax on individual incomes.

SOCIAL SERVICE is organized philanthropic activity to promote human welfare. Its objective is to help those who, because of personal factors or forces within their cultural, social, and economic environment, are prevented from realizing their fullest potential. As a professional discipline and social institution, social service has emerged out of centuries of man's humanitarian efforts to help his fellow man. For the history of these efforts in the form of personal and religious charity *see* PHILANTHROPY. For the recognition by the Elizabethan Poor Law of 1601 of public as well as moral and religious responsibility to aid those in need *see* POOR LAW. For the development of modern programs *see* SOCIAL WELFARE and CHILD WELFARE. *See* also POVERTY; SOCIAL SECURITY; WELFARE STATE.

Following a brief survey of the historical background of social service, this article deals with its development as a professional discipline and the emergence of the profession of social work.

HISTORICAL BACKGROUND

The desire of people to help one another in times of need and stress is deeply ingrained in the human race. The helping hand of neighbour to neighbour, the sporadic impulse to help as expressed in the dropping of a coin in an outstretched hand, the charitable acts which characterize certain seasons of the year all reflect man's humanity to man. Throughout the ages and in all parts of the world, these humanitarian impulses have marked the beginnings of social service.

Personal Charity.—Mutual aid and individual charity can be considered early social service. The giving of alms was accepted as a religious duty or as a self-imposed social obligation of the privileged toward the underprivileged. In some countries, particularly those influenced by Islamic traditions of mutual aid and neighbourly love, personal charity continues as a primary motivating force and predominant charity method. Recognition of deficiencies in almsgiving came early to the countries of the Western world. As early as the 16th century, Juan Luis Vives in Belgium and, a little later, St. Vincent de Paul in France sought to relieve destitution through orderly methods of investigation of the needs and problems of the poor. The Elizabethan Poor Law of 1601 in England established the principle of public responsibility for those in need, a principle which was adopted by the American colonists who carried the English poor law to the new land.

Organized Charity.—Changing economic and social conditions in 19th-century England and America brought new problems of massive poverty and, also, new approaches toward solutions of the problems of destitution. These attempts flowed from compassion and paternalism, strongly tinged with a desire to protect society from the risks and consequences of pauperism. The Rev. Thomas Chalmers in Glasgow saw in public poor relief a permanent obstacle to the development of thrift, industry, and temperance in the poorer classes. In 1819, he put forward in St. John's parish his proposals to solve the problem of poverty. His program, which combined direct personal service to the poor with careful investigation of need and resources, demonstrated to the satisfaction of many the power and superiority of private charity. Chalmers' work did not long survive his departure from Glasgow, but the ideas he espoused found fertile soil in the charity organization movement, fostered by Edward Denison, Octavia Hill, and other leading exponents of private charity.

The London Charity Organisation Society, founded in 1869, became a potent force under the direction of Charles Stewart Loch who served as secretary to the council of the society from 1875 to 1914. It brought to the forefront a new conception of social service as an organized activity designed to lead individuals and families to self-help and economic independence through thrift, industry, and strength of character. In the 11th edition of *Encyclopædia Britannica* (1910–11), Loch stated the principles and outlined the methods that guided this movement. The principles and methods of modern social service have expanded and changed in many ways, but the roots lie in the charity which Loch described as "a science based on social principles and observation." He pointed out that charity should be organized and given a definite social purpose to which members of the community must be associated if the purpose is to be fulfilled. He stated, further, that this "depends on the recognition of common principles, the adoption of a common method, self-discipline and training, and co-operation." In such ideas and in the use of volunteer friendly visitors, the charity organization movement laid the foundations for the later development of a body of knowledge and a methodology for the profession of social service and for the emergence of the professionally educated social worker.

The charity organization movement found welcome acceptance in the United States. By 1900 there were 150 societies in the U.S. operating under charity organization principles. The charity organization movement contributed significantly to the development of social service for individuals and families and to the aims and methods of community organization.

Other movements in that century also gave birth to programs and ideas that did much to shape social service as it is known today. In the 1830s Samuel Gridley Howe began his work with blind, deaf-mute, and mentally defective children. His successful demonstration of their educability laid the groundwork for increasingly effective training and social service for the handicapped. In the same period the inspired crusade of Dorothea Lynde Dix on behalf of the insane demonstrated that mental illness is a disease capable of treatment and cure. The child-saving movements fostered at mid-19th century by William Pryor Letchworth and Charles Loring Brace to rescue children from the almshouses and the slums gave rise to child-serving agencies and child welfare programs. A strong reform dimension was added to philanthropy at the end of the century by the social settlement movement. Initiated in London by Samuel Barnett at Toynbee Hall, the movement was brought to its fullest flower by Jane Addams at Hull House in Chicago. From it social service derived the beginnings of group work, a community approach, and social action.

Mitigating Misery.—The 19th-century prototypes of the social service worker centred their efforts on mitigating human misery, created and often cruelly neglected by a rapidly changing

social and economic order. The underlying causes of the distress that charity workers and poor law officials were attempting to alleviate received too little attention. In fact, officials' and charity workers' perception of their task reflected content with the society in which they lived. They saw little amiss in holding the destitute responsible for their destitution. Jane Addams (*q.v.*) summed up the prevailing philosophy of the times in these words:

> Formerly when it was believed that poverty was synonymous with vice and laziness, and that the prosperous man was the righteous man, charity was administered harshly with a good conscience; for the charitable agent really blamed the individual for his poverty, and the very fact of his own superior prosperity gave him a certain consciousness of superior morality. ("The Subtle Problems of Charity," *The Atlantic Monthly*, 83:163–178, 1899.)

The palliative and protective aspects of social service have by no means disappeared, even in affluent societies. The services that are rendered and the views about relationships that should exist between the giver and the beneficiary have undergone great change. In some countries, notably in the less-developed regions of the world, social service may still focus on economic dependency and the conditions associated with it. The problems in those countries may be similar to many of the problems of an earlier period in the Western world. To Western experience, the countries of Asia, Africa, and Latin America are adding their own evolving experience in raising the levels of living of predominantly rural populations. Indigenous methods, such as community development, can provide new solutions to the age-old problem of poverty, enlarging social service experience throughout the world.

Prevention and Social Reform.—A marked shift in emphasis in the conception of social service became apparent at the turn of the 20th century. Passive adjustment to the status quo had begun to arouse vague feelings of discomfort in the charity workers and clearly did not satisfy the Hull House reformers who pioneered for social justice in the late 19th century and the opening decades of the 20th. (*See* also HULL HOUSE; SOCIAL SETTLEMENTS.)

Crusading reformers were not new in social service. In other countries and in earlier periods there were men like Robert Owen and Lord Shaftesbury who battled for factory and child-labour legislation. Crusaders like Elizabeth Fry and John Howard devoted their lives to the reform of the prison system. Beatrice and Sidney Webb, in London, shared a vision of a better life; Jacob Riis, in New York, worked to wipe out the slums; other settlement houses were hard at work in New York, Boston, Pittsburgh, Buffalo, and Cleveland. But in that small group in Chicago there was a combined force and intensity that had never before in social service been mustered so successfully in the interests of the common man.

Prevention was the byword. Through slum clearance, decent wages and working conditions, abolition of child labour, juvenile courts for child offenders, mothers' pensions, and similar means they sought to remove the causes of economic distress and social breakdown. Their leadership associated social service with the emerging liberalism of the times. Private charity was not always sympathetic to their goals, particularly those that involved public support and administration of social service programs, but the tide was running in favour of social reform.

In the United States the first White House Conference on the Care of Dependent Children, called by Pres. Theodore Roosevelt in 1909, paved the way for the protection and care of dependent children in their own homes through publicly supported and administered mothers' pensions; the first laws were passed in Illinois and Missouri in 1911. With that step and with the earlier enactment of the first workmen's compensation (*q.v.*) law, a new and better future was charted for the public social services. The road was open to the later development of the social insurance, public assistance, and public child-welfare measures embodied in the Social Security Act of 1935. (*See* further SOCIAL SECURITY.)

Methods of Work.—The paternalistic and moralistic charitable work of the 19th century would be repugnant to the modern social worker. The early work contributed concepts that are still of value, however: the concept that each person and his needs represented a unique situation; helping people to help themselves; the value of personal relationship expressed in Octavia Hill's phrase "not alms, but a friend"; and friendly visiting, early confirmed as a key method of helping through personal influence. The importance of knowledge of the person in his social situation was demonstrated in procedures for investigation and in painstaking assemblage of information. When the experience of that period was formulated by Mary Richmond in *Social Diagnosis* (1917), it was clear that social service had acquired the professional method of social casework (*see* below).

Organized Agencies.—Charitable and philanthropic work was represented, in the early decades of the 20th century, by many agencies, programs, and services under a variety of auspices, governmental and nongovernmental, sectarian and nonsectarian. They included child welfare, family welfare, public welfare, juvenile courts, probation and parole service, medical social service, school social service, mental health, programs for the handicapped and other special groups such as the aged, settlement houses, and leisure-time services.

Community Organization.—An early aim of the charity organization movement had been the coordination of charitable efforts to eliminate duplication and overlapping. The larger coordinating effort was later assumed by councils and federations of charities and philanthropies that came into being early in the 20th century. Social planning and federated fund raising were the features of these agencies. Their experience in organizing communities to create and support social welfare programs gave to social service the professional method of community organization.

The reform movement of the early 20th century highlighted social action. From their day-to-day exposure to the consequences of a faulty social order, the settlement house workers and, increasingly, the charity workers assumed responsibility for assessing causes and proposing remedies. Social research and social action followed naturally the shift in attention from deficiencies in the poor to insufficiencies in their environment.

The Workers.—Charity workers were a mixed lot but distinguishable by the end of the 19th century. Clergymen of many faiths, volunteer friendly visitors, wealthy and influential citizens on agency boards and state boards of charities and corrections, overseers of the poor, and paid charity agents were associated in a common effort. But as yet there was no bond of common education or united purpose to bind them together.

Inspired by the teaching and personal influence of Francis G. Peabody, young graduates of Harvard University made a career of charitable work; so, also, did men past middle age; and many women who started as volunteers remained as paid workers. This heterogeneous group founded the National Conference of Charities and Corrections, now the National Conference on Social Welfare. The paid workers of Boston and Philadelphia early met in "Monday" clubs for the purposes of professional association.

The expanding charity organization societies early faced the problem of training volunteer visitors and paid agents. A number of British and American pioneers in philanthropic work were able economists and social philosophers who left a considerable volume of reports and recorded experience. Their commitment to "scientific charity" produced theories and principles that were available to the neophyte. Mary Richmond was one of the first to proclaim that good intentions and common sense were not enough for charity work. She saw the limitations of apprenticeship programs that had developed in both Britain and the United States. With her successful proposal in 1897 that a training school of applied philanthropy be established, charity work took a giant step in the direction of social service as a profession.

EMERGENCE OF SOCIAL SERVICE AS A PROFESSION

Mary Richmond's call for special preparation for charity work met with immediate response. The New York Charity Organization Society launched a summer school of philanthropic work in 1898. A more significant step was taken in 1899 when an Institute for Social Work Training was established in Amsterdam and offered a two-year course combining study of general sociological knowledge, socio-economic problems, and legislation with supervised practical training in various fields of social work. By 1903

the training activities of the London Charity Organization Society had led to the development of a two-year program of theory and practice in a formal School of Sociology. In 1904 the New York Charity Organization Society offered a one-year program in the New York School of Philanthropy, the first school of social work in the United States (now the Columbia University School of Social Work). Boston followed New York in 1904, Chicago and Berlin in 1908. The movement spread rapidly within Europe, throughout the United States and by 1920 it had reached Latin America, where the first school was established in Santiago, Chile.

Charitable and philanthropic work had become generally known as social work or social service; its personnel were identified and designated as social workers. The road to professional status was open but rugged. In 1915 Abraham Flexner disturbed the growing confidence of social service in its professional status with his conclusion that it met some but not all of the criteria of a profession. He noted particularly that it did not have its own "technique communicable by an educational process."

A significant milestone was reached with the appearance in 1917 of *Social Diagnosis*, Mary Richmond's outstanding contribution to social service as a professional discipline. The systematic method of social study and diagnosis which she outlined gave to social service distinctive processes and techniques thereafter considered communicable in formal education programs.

With the entry of the United States into World War I, social service was faced with assisting servicemen's families in need and, later, servicemen under psychiatric care. At the same time psychiatry made a new and tremendous impact upon social service. Virginia Robinson's *Changing Psychology in Social Case Work* (1930) cited the major contributions of psychoanalytic psychology to social service: (1) the concept of determinism in psychic life; (2) emphasis on the need (as opposed to the intellectual) basis of human behaviour; and (3) insight into the effect of family relationships on individual development. To these should be added a revolutionary new concept of the meaning and professional significance of the relationship between the social worker and his client as the medium through which change in the person and his social situation could be effected.

Mary Richmond's formulations represented a synthesis of the knowledge of her time and provided primarily a sociological basis for the practice of social casework. The family in its social environment lay at the centre of her concern. Psychoanalysis supplied a psychological basis that, for a number of years, centred attention on the individual, almost to the exclusion of all else. In the depression of the 1930s, social service was brought back to its primary concern with man interacting in his social situation. It had by that time emerged as a professional discipline with its own communicable methods of practice.

Awareness of professional identity led to the establishment of national professional associations. The schools of social work in the United States and Canada launched in 1919 a central standard-setting and service organization, now the Council on Social Work Education. As early as 1918 American practitioners came together in various associations and, in 1921, they established the American Association of Social Workers, the major predecessor of what is now the National Association of Social Workers.

Knowledge, Methods, and Scope.—United Nations surveys of training for social work indicate a large measure of international agreement on the basic body of knowledge and the skills required by social workers. The humanities and the social and behavioural sciences contribute to the social worker's general understanding of man and his environment. From medicine (particularly psychiatry), psychology, law, and education, knowledge is borrowed and reshaped to the purposes of social work. Increasingly, however, the social work profession is developing its own distinctive body of knowledge.

As already noted, casework early emerged as a professional method in social work practice. Mary Richmond's first formulation (1915) stated simply that "Casework is the art of doing different things for and with different people by co-operating with them to achieve at one and the same time their own and society's betterment." The many definitions that followed have clarified and refined the meaning of casework as a complex helping and problem-solving process, but all contain certain essential ingredients: (1) the social worker's commitment to the worth of the individual and his belief in man's capacity for growth and change; (2) the artistic use of knowledge in a professional relationship in which the individual is helped to cope more effectively with his problems; and (3) effective use, in the problem-solving endeavour, of all relevant resources within the social environment and within the person seeking help. Social workers also may lead groups to help in individual and group achievement. Community organization as a professional social work method shares with casework a common ancestry in the charity organization movement. At one time seen largely as a process of adjustment between community resources and community welfare needs, community organization has begun to emerge as a means of helping the community to engage in a systematic process of planned change toward community improvement.

The West, particularly the United States and Canada, pioneered in the delineation of the professional social work methods of casework, group work, and community organization. All countries which recognize social service as a professional discipline have used one or another or all three of the methods in translating social goals into direct service to people. Dame Eileen Younghusband of the United Kingdom noted in the third United Nations survey of social work training:

> The conclusion would seem to be that in casework, group work and community organization and certain aspects of community development, as these have evolved in different cultural settings, some fundamentals of working with people have emerged which hold true under all circumstances. (United Nations, *Training for Social Work: Third International Survey* (1959, p. 95.)

Early concern with broad social reform and later emphasis upon individual treatment are more and more becoming fused into a unified effort to induce social as well as individual change, to prevent social problems as well as to alleviate their end results, to affect the destiny of large population groups as well as to help individuals and families and small groups. This transitional state is also reflected in new attempts to synthesize sociological and psychological knowledge and to undergird professional practice with social work's own developing theory.

The emerging new conception of social service as a force and instrument in the promotion of planned social change enlarges the scope of professional social work activity, which, traditionally, has been associated with such fields of practice as child and family welfare, medical and psychiatric social work, school social work, corrections, group services, community welfare planning, industrial social work, and various forms of social or public assistance. Social workers have provided protective, palliative, and rehabilitative (and, to a lesser extent, preventive) services for the disadvantaged, the disabled, the displaced, the unemployed, the mentally, emotionally, and physically ill, the criminal and the socially irresponsible, the deprived young and the neglected old, and all the ugly results of social disorganization and social injustice. To these significant age-old tasks, the social work profession, in the view of practitioners, should now add newer responsibilities of joining with other disciplines to attack mass poverty at its source, to seek out and prevent the problems that blight the lives of people in affluent as well as struggling new societies, and even, it has been said, to reshape social structures in directions thought to provide new and better opportunities for productive and satisfying living. A United Nations survey of programs of social development disclosed that within the first ten years after World War II responsibility for social service as an instrument of social development had been proclaimed in new constitutions or introduced, by amendments, into the former constitutions of 45 countries.

Social Service Personnel and International Organization.—Nations old and new share the goal of staffing their social services with professional personnel, but in no country are there enough qualified workers to meet the need. The United Nations early recognized that steps must be taken through technical assistance and other means to promote social work education if social welfare

policy is to be translated into effective social services. International fellowships, consultant services, regional seminars, and special studies and training projects have been introduced.

Approximately 300 schools of social work were in operation in over 40 countries in 1950 when the United Nations made its first international survey of training for social work. Fifteen years later, more than 400 schools were preparing social workers in more than 50 countries and the totals were increasing every year. Most of the growth occurred in Asia and the Middle East.

The pattern in the United States and Canada places social work education as a graduate professional discipline within universities, which grant a master's degree upon completion of a two-year program. An increasing number of graduate schools of social work in the United States also offer programs leading to the doctoral degree. In other parts of the world, schools of social work may be organized within or in relation to universities (usually at the level of undergraduate study) or as independent educational institutions under government, religious, or secular auspices. The university pattern of social work education appears to be finding increasing acceptance in Asia and some parts of Latin America and Africa, where schools of social work are relatively new.

The International Conference of Social Work brings together in a biennial world forum persons concerned with social welfare problems. The International Association of Schools of Social Work sponsors a biennial congress and a range of activities designed to promote high standards of professional education. The International Federation of Social Workers brings together the practitioners affiliated with national associations of social workers. Each of these organizations has been granted consultative status by the Economic and Social Council of the United Nations. Together, they cooperate in many areas, including the publication of an official journal, *International Social Work*.

Social service is influenced in the countries of the world by social, political, economic, and cultural forces that vary greatly from country to country. It is also influenced by an awareness that peoples everywhere share common needs and aspirations.

SOCIAL SETTLEMENTS are neighbourhood social welfare agencies, also called settlement houses, community centres, or neighbourhood houses, centres, associations, or guilds. In Great Britain there are both residential settlements, where members of the staff live as well as work, and community centres founded by city and borough councils. Settlements, under a variety of names, are to be found in most countries of western Europe and in Southeast Asia and Japan.

History.—The settlement movement began with the founding of Toynbee Hall (*q.v.*) in London in 1884. Samuel A. Barnett (*q.v.*), then vicar of St. Jude's Parish, invited a number of university students to join him and his wife in "settling" in a deprived area. The movement spread to the United States when Stanton Coit, an early visitor to Toynbee Hall, established Neighborhood Guild, now University Settlement, on the Lower East Side of New York City in 1886. In 1889 Jane Addams, another Toynbee Hall visitor, and Ellen Gates Starr bought a residence in the Near West Side of Chicago, and started Hull House (*q.v.*). In the same year Jane E. Robbins and Jean Fine (Mrs. Charles B. Spahr) opened the College Settlement in New York City. Two years later Robert A. Woods established Andover House, later called South End House, in Boston. The movement spread to other countries mainly through the influence of visitors from those countries to settlements in England or the United States.

Purposes.—The purpose of a settlement is the development and improvement of a neighbourhood or a cluster of neighbourhoods. It differs from other social agencies in that it is concerned about neighbourhood life as a whole. In a sense the neighbourhood is its client. Settlements seek to develop harmonious relationships among community groups of different cultural, economic, religious, and social characteristics. While they may be sponsored and supported by a religious organization, their purpose is to serve all kinds of people who live in the neighbourhood.

Settlements try to help people act together to improve their living conditions and environment. Under the leadership of pioneer workers such as Lillian D. Wald (*q.v.*) at the Henry Street Settlement in New York City, Jane Addams, and the many persons who served as residents and volunteer leaders (Joseph Moss and Sophonisba Breckinridge, to mention only two from Hull House, for example), social settlements helped win legislation providing for juvenile courts, mothers' pensions, workmen's compensation, and the regulation of child labour; they promoted playgrounds and recreation centres, maternal, infant, and child health clinics and services, and adult education programs, and took part in housing and other reforms.

Services.—The services of settlements, while they vary, are all committed to bringing together people who live in the same geographical area for the purpose of following common interests and of improving neighbourhood life generally. The settlement's program is determined by the needs and interests of the neighbourhood, changing in accordance with changing conditions. One settlement serving two or more neighbourhoods that differ in composition or condition may offer different services to each. In general, services fall under three main categories: work with individuals and families, with groups, and with, or in behalf of, the neighbourhood as a whole.

Work with Individuals and Families.—Informal counseling and home visiting are done by almost every member of a settlement's staff. Where specialized skill is needed, settlements have employed caseworkers, psychologists, psychiatrists, home economists and vocational counselors. In neighbourhoods lacking adequate health services, medical or dental clinics have been provided, and settlements have campaigned for the extension of public health services. Nursery schools and day care for children have been provided for families needing them because of employment of mothers or other reasons.

Work with Groups.—Group work is intended to enrich the social life and experience of the individual members and to provide opportunities for the group as a whole to contribute to neighbourhood improvement. Settlements serve both membership groups sponsored by the settlement and autonomous neighbourhood organizations. Membership groups—including friendship

clubs, classes, athletic teams, and interest or hobby groups—enroll people of all ages, interests, and abilities. The settlement provides a place to meet and a group leader, teacher, or coach, and, for younger groups program materials and equipment. Members join for amusement, and often for personal and social development. The settlement's worker seeks to develop feelings of neighbourliness, mutual respect, and social responsibility. Such group work requires most of the settlement's space and staff time.

Independent neighbourhood organizations and groups often request certain services of the settlement, sometimes the use of a room for meetings, sometimes the guidance of a staff member. Settlements have helped to develop parent-teacher associations in neighbourhood schools; have helped local churches to develop social and recreational youth programs; and have provided guidance in the development of youth, recreational, or welfare programs for labour unions and veterans, civic, and fraternal organizations.

Work with the Neighbourhood.—At Toynbee Hall and at certain settlements in other countries, some professional staff members as well as university students and other volunteer workers live in the settlement's building so that they may become in fact as well as in feeling a part of the neighbourhood. In all settlements, the staff workers are expected to become familiar with neighbourhood people, conditions, and problems and to identify themselves with attempts to improve conditions, working with the people, with governmental officials, and with citizens of the larger community. They encourage and help local individuals and groups to organize and to take action to secure enforcement of housing, safety, and sanitation codes. They make available to the neighbourhood people reliable information about proposed public improvements, such as highways, slum clearance, and urban redevelopment, and encourage them to express their concerns to governmental agencies and officials.

Neighbourhood action may be directed toward legislation as well as to administrative decisions. Settlements seek to acquaint social welfare and other planning bodies with facts about living conditions and social needs in their neighbourhoods, and they participate, through their representatives on community welfare councils or similar groups, in social planning for cities and metropolitan areas. Social settlements are thus agents of social reform.

Administration.—The responsibility for operating a settlement is vested in a board of directors composed of citizens, not all of whom live in the neighbourhood. The board establishes policy and is responsible for securing and administering funds. The administrative and supervisory staff is usually composed of persons with professional education in social work. Workers trained in informal education, nursing, early childhood education, physical education, and recreation also are employed extensively.

In the United States most settlements secure financial support from Community Chests or United Funds. Support may also be provided by endowments, in both the United States and Great Britain; by government agencies, especially in Europe; by local, national, or international religious organizations; by industrial corporations and private individuals; and by charitable trusts and foundations.

Buildings vary greatly. Many settlements have a modest central building but use rooms in buildings owned by housing authorities, public schools, and churches for some of their activities. Clubs and other groups may meet in private homes of members. Leadership, rather than meeting space, is considered the primary contribution of the settlement. However in a congested and deteriorating city neighbourhood, the settlement house often furnishes a hospitable common ground where diverse and transitory groups gain a feeling of security they cannot find elsewhere in the neighbourhood.

The Settlement and the City.—Historically the social settlement was a method of solving problems peculiar to urban living, particularly for the poor. Crowded conditions, preoccupation with one's own urgent problems, and the lack of concern of one's neighbours made difficult the maintenance of neighbourly feeling and responsibility characteristic of rural and village life. In the United States, before the adoption of the Quota Laws of 1921 and 1924, waves of immigrants successively crowding into transitional, depressed, or slum areas faced additional problems of coping with strange customs and a strange language. The settlement attempted to restore under urban conditions some sense of belonging and of caring which seemed necessary in a humane society.

The difficulty of finding financial support in smaller, poorly organized (for purposes of social welfare) communities had tended to confine settlements to metropolitan areas. However, because of the concern of religious organizations particularly, some small agricultural and newer industrial communities have been helped to establish and maintain a community centre, similar to a settlement. Dispersion of industry outside metropolitan areas has brought into being new towns which need this general-purpose type of community service. Communities of migratory agricultural workers, particularly where children are involved, have claimed the attention of religious organizations in the United States, with the result that a settlement type of work has been established.

City, National, and International Organizations.—In the larger cities of the United States and in some cities of Europe the settlements have formed voluntary city federations. In most instances, these have not employed any staff but have provided opportunities for employed workers especially, and for some board members, to discuss and sometimes act together on common problems. The first such federation was formed in Chicago before the turn of the 20th century and the second in New York City shortly thereafter. In a few smaller cities all of the settlements have combined to form one agency which operates several centres in different neighbourhoods.

The founders of early settlements in the United States met periodically, especially with reference to conditions which seemed to require national co-operation and action of the federal government. In 1911 they established the National Federation of Settlements, with Jane Addams as its first president. Robert Woods of South End House, Boston, was the first (unpaid) executive secretary. From 1929 the federation employed a full-time executive secretary to facilitate the co-operation of the settlements on matters of national concern and to help improve standards of neighbourhood work throughout the country. The British Association of Residential Settlements was established for the same purposes. Several European countries also have national organizations of settlements, most of them founded after World War II.

The first International Conference of Settlement Workers, held in London in 1922, led to the organization in 1926 of the International Federation of Settlements. Except for a hiatus immediately before and during World War II, this federation has met every four years. After World War II its headquarters were at the French Association of Social Centres in Paris till 1956, when they were moved to the Dutch Federation in Utrecht. The International Federation is represented by observers at the United Nations.

SOCIAL WELFARE is considered, in this article, as including the attempts made by governments and voluntary organizations to help families and individuals by maintaining incomes at an acceptable level, by providing medical care and public health services, by furthering adequate housing and community development, by providing services to facilitate social adjustment, and by furnishing facilities for recreation. In addition, social welfare includes legislation and facilities designed to protect those who

might be subject to exploitation, and to care for those groups considered to be the responsibility of the community. Educational services, usually considered as social welfare provisions, are covered in other articles (*see* EDUCATION [ARTICLES ON]).

All nations have developed social welfare services as they have moved from agrarian to industrial economies. In preindustrial societies the family group cares for its own young, its own aged, its own sick and disabled; the food and shelter available are distributed among all members; social maladjustment is dealt with by the family. Such a system of mutual responsibility becomes impossible under modern industrial organization, which demands mobility and the congregation of the population in crowded urban centres. It has become necessary, therefore, for society to provide substitutes in the form of social services, subsistence, medical care, and protection. In all countries these have been provided by both private associations and the state.

HISTORY

The early history of social welfare in most western nations is the history of the Poor Law (*q.v.*) and of the private charities and foundations which supplemented it. (*See* also CHILD WELFARE.) Until the latter half of the 19th century, therefore, most social welfare services carried only negative implications. They were intended to assuage abject poverty and suffering; to prevent epidemics of deadly disease; to protect the population against begging and thieving; to appease the lower classes and so prevent revolution and maintain order. Earlier improvement in social welfare services was deterred by two enduring concepts: first, that government should avoid to the greatest extent possible any interference with the economy or social relationships; second, that all was well with the economic and social organization and that poverty or social maladjustment could be attributed to personal inadequacies or moral infirmities.

These two concepts were emphasized during the 18th-century Enlightenment and became most effective as the middle classes obtained political power. The demand for limited government, a reaction to the excesses of monarchies and mercantilism, was, of course, at the heart of the struggle for modern constitutional government. Social welfare services, except those provided by private benevolence, could not be developed as long as the function of government was thought to be limited to the protection of private property and the conduct of foreign affairs. Less theoretical concern about the propriety of governmental responsibility for social welfare services was expressed during the latter part of the 19th and early 20th century, particularly in the United States. There the public services were usually manned by political appointees with no civil-service tradition or security of tenure. Graft and other political chicanery were to be expected.

The second concept had its origins in Judaeo-Christian philosophy and was articulated in secular terms during the 18th century. Recognizing first the supreme importance of the individual, the philosophers of the Enlightenment saw the greatest fulfillment of the individual and therefore the greatest welfare of society in the operation of the free market. Since each individual, according to natural immutable laws, was bound to operate rationally in his own self-interest, any interference with the freedom of an individual to choose, for example, a path which leads to poverty instead of wealth would be in violation of natural law and inimical to the general welfare.

These ideas, which found ready acceptance among the middle classes, were buttressed by the theories of such men as Joseph Townsend, English clergyman, geologist, and author of *A Dissertation on the Poor Laws* (1786), who considered the spectre of poverty and suffering necessary to entice men to work at menial occupations; T. R. Malthus, who considered any aid given to the poor as encouraging them to increase their numbers and so to diminish the subsistence available to the rest of the population; and David Ricardo, who saw in the "wage fund" the impossibility of improving the condition of the labouring classes. Also delaying improvement in social welfare was Protestantism in general and Puritanism in particular, with its emphasis on hard work and frugality and its equating of worldly success with divine election. The acme of this trend in ideas was achieved by the Social Darwinists during the last half of the 19th century. Herbert Spencer, for example, believed that men who advocated social welfare measures were "blind to the fact that under the natural order of things society is constantly excreting its unhealthy, imbecile, slow, vacillating, faithless members." Suffering by some must be endured so that the welfare of the many might eventually be achieved.

Poor Law Reform (1834).—The Poor Law reform of 1834 in England was the most specific expression in legislation of such ideas concerning the nature of poverty and the proper role of the state in its relief. All relief to the able-bodied in their own homes was forbidden, and all who wished to receive aid must move into the workhouse. This law established officially the principle of "less eligibility" which was to plague the development of social welfare in the United States and England for the next hundred years. According to this principle—since poverty was due to individual fault, since any encouragement to laziness or thriftlessness was a threat not only to the proper operation of the economic system but to the very survival of the nation—all efforts should aim at making the application for and receipt of poor relief as odious and degrading as possible. In the United States during the early 19th century no such national statement could have been expected because of the limited powers and responsibilities of the federal government at that time. The Yates Report of 1824 in New York State and the Quincy Report of 1821 in Massachusetts, however, both recommended that all the poor be cared for in public almshouses, the latter stating "that of all the modes of providing for the poor, the most wasteful, the most expensive, and most injurious to their morals and destructive to their industrious habits is that of supply in their own families."

Voluntary Welfare.—The ideas of the Enlightenment, which were so congenial to the middle classes during the 19th century, also had the effect of encouraging voluntary social welfare. While the discipline of *laissez-faire* economics and devotion to natural law impelled the commercial classes to permit suffering and allow poverty to go unrelieved by government, the humanitarian aspects of the Enlightenment emphasized the importance of good works and the benefits of charity to the giver. Benjamin Franklin, for example, was an insistent opponent of all forms of public relief yet was a well-known philanthropist whose time and money had been given to the creation of a large number of welfare organizations. This humanitarianism also caused men of influence to be repelled at the condition of the working classes resulting from the free operation of economic forces. The paradoxical quality of their attitude toward social welfare is illustrated by the fact that in England the first substantial Factory Act, providing for the appointment of factory inspectors and requiring that employed children between the ages of 9 and 13 attend school for two hours each weekday, was passed during the year prior to the restrictive Poor Law reform of 1834.

Lavish expenditures for private charity were possible during the early period of industrialization because of the accumulations of great wealth in the hands of a few individuals. Many hospitals, schools, universities, and charitable foundations were endowed in the era of unrestricted capitalism in England, the United States, and western Europe. The unrestrained giving typical of the 19th century, however, was disturbing to the conscience of the middle-class liberal as it too could pauperize the recipients, discourage thrift, sacrifice, and hard work, and so interfere with the free operation of natural economic law. Their answer was "scientific philanthropy" which aimed at separating the "deserving" from the "undeserving" poor and assisting the former to self-support. In England and the United States this rationalization of benevolence was carried on by the Charity Organization societies.

The humanitarian impulses of liberalism also gradually led to a less rigid attitude toward the supposed evils of public poor relief. While the leaders of private charity were concentrating on saving the "deserving" poor from the evils of the workhouse or almshouse, the public authorities were attempting to make a similar distinction. Special provisions were made first for the mentally ill, then for dependent children. Relief in their own homes was permitted the aged and infirm. By the early 20th century in En-

gland and later in other countries special provisions were instituted for the able-bodied who were unemployed through no personal fault (*see* UNEMPLOYMENT INSURANCE). By categorizing the poor on the basis of the supposed causes of their destitution, it was possible to relieve suffering without moral damage to the recipients of relief and without interfering with the free operation of the economic system.

Social Insurance.—Even more acceptable to the middle classes than categorization of the poor was social insurance. Here was a term and a concept borrowed from the commercial world. Social insurance would place the relief of poverty on a "businesslike" basis. It would encourage thrift and provision for the future and would in no way pauperize the recipients of its benefits. Social insurance in most countries, therefore, developed during the early 20th century and has gradually been expanded to include most common risks and to cover most of the population. Poor relief (*i.e.*, general assistance for the needy who do not qualify for one of the categorical programs for aid to dependent children or to the aged, blind, or disabled), however, has never recovered from the slander of the 19th-century liberals and remains in most places a "residual category."

Credit for the development of modern social welfare services should not be given to the humanitarianism of the middle classes exclusively. The rise to political influence of the urban working class was perhaps more important. It was not possible to convince the labourers that an economic system which brought hardship and suffering to so many of their numbers was what nature intended or was divinely sanctioned. They had experienced or witnessed poverty which could not be attributed to moral infirmities but was the result of economic conditions beyond their control. The evil of government intervention was much less serious to them than the evils of free competition bridled only by monopoly. The impact of the rise of organized labour to a position of political significance can be seen most clearly in the case of England. There the acceleration in the enactment of labour and social welfare legislation coincided with the entrance of the trade unionists into Parliament beginning in 1874.

On the continent of Europe the influence of socialism was probably more effective than either the labour movement or the humanitarianism of the liberals. In the United States the influence of organized labour was not crucial to the furtherance of social welfare measures until the 1930s. The earlier advances in the U.S. can be attributed to agitation by middle-class reformers and intellectuals.

In a sense it can be said that modern social welfare programs are the result of willingness on the part of both the middle classes and the urban workers to abandon their apocalyptic hopes and to attain their ends within the framework of constitutional democracy. The middle classes were the first to move from their original position. As the progress of industry led to larger accumulations of capital, men with small or middle-sized financial resources found it harder and harder to survive in competition with wealthy rivals. In practice it became apparent that the free market was an obstacle to all but a few. Although free competition continued to be considered the basis of society, genuinely competitive conditions called for positive action by the state, for tariff protection and antimonopolistic and other forms of remedial legislation.

By the 20th century most socialists also realized that they would be able to achieve their aims only by reforming the existing system through established institutions, and they too turned to positive state action. The working-class movement had been able to accomplish much improvement in working and living conditions by strikes and other nonpolitical means, but these gains could be consolidated only through legislation. Organized labour had also been able to protect its members to some extent from the risk of sickness, injury, old age, and unemployment by collective bargaining and by mutual benefit societies, but in order to provide wide coverage and adequate benefits it was necessary to turn to compulsory insurance which could be enforced by the taxing power of the state and subsidized from general revenues.

In the United States the movement from the poor laws to modern social welfare provision followed much the same pattern as in England and on the continent but at a much slower pace, probably because the nation was dominated almost exclusively by the middle classes during the 19th and early 20th centuries. Not only were there no groups comparable to the nobility and peasantry of Europe but, in addition, a politically conscious and influential labour movement did not appear until relatively late. Early reforms, therefore, were essentially the product of middle-class activity and were concerned more with the regulation and control of business and with attempts to improve legislative and administrative processes than with the provision of social welfare services. Only with the economic depression of the 1930s and the rise to political influence of the labour movement did public social welfare arrangements begin to equal those of Europe.

The change in attitude toward the poor and other unfortunates and toward the responsibility of the community which occurred in western nations generally between the early 19th century and World War I cannot, of course, be attributed solely to the disillusionment of the middle classes or to the extensions of suffrage which brought the influence of the working classes to bear directly upon public policy. Other forces subtly altered the outlook of the public toward the social ills that beset nations that were being industrialized rapidly. For example, there was the fear of revolution threatened by socialists, communists, and anarchists. Concern for the poor and for the plight of the working classes was encouraged by the papal encyclical *Rerum novarum* (1891) and by the Christian Socialists; in the United States the Social Gospel movement encouraged Protestants to seek a solution to the social problems of the day (*see* LEO: *Leo XIII;* CHRISTIAN SOCIALISM). Improved means of communication and the spread of literacy brought to increasing numbers of people the facts of poverty and suffering and the remedies proposed by militant reformers. Recurrent business depressions began to dispel the idea that all was well with the economic and social system and that poverty could in many cases be attributed to individual fault.

Whatever the causes, the results of this change in attitude can be illustrated by the extent to which social insurance measures had been adopted by western industrialized nations prior to 1914. Laws providing compensation for industrial accidents were in force throughout practically all of Europe, in many of the British dominions and colonies, and in about half of the United States. There were compulsory sickness insurance programs in Germany, Austria, Hungary, Great Britain, and Norway and voluntary insurance was subsidized by government funds in most of the remaining European countries. Compulsory old-age insurance was operating in France and Germany. The first compulsory unemployment insurance system had been instituted in Great Britain, and subsidized voluntary unemployment insurance coverage was available in many large European cities and nationally in Norway and Denmark.

In most countries the progress of social insurance continued after World War I. By 1930 practically the entire industrialized world had workmen's compensation in some form or another. Practically all of Europe had some form of social health insurance. Of the 27 countries in Europe, 23 had either old-age insurance or old-age pensions or both. By 1935, 19 European countries had nationwide unemployment insurance, either compulsory or voluntary. Also in 1935 the United States adopted the Social Security Act, which provided a nationwide program of contributory old-age insurance, unemployment insurance, grants to the states for public assistance to the aged, the blind, and dependent children, and for various health and child welfare services. (*See* further HEALTH INSURANCE; MEDICAL CARE, GOVERNMENT; SOCIAL SECURITY; WORKMEN'S COMPENSATION.)

Other Developments.—Social welfare developments during the early 20th century were not, of course, limited to those in social insurance and public assistance. A few examples concerning the welfare of children will illustrate the range and nature of other improvements. As children were removed from the workhouses and almshouses there was resort first to free foster homes and private and public specialized institutions. Later, emphasis was placed on boarding homes supervised by professionally staffed social agencies. The first juvenile court was established in Chi-

cago in 1899 and the idea spread rapidly throughout the world (*see* CHILDREN'S COURT). Great Britain and Canada adopted juvenile court laws in 1908, France and Belgium in 1912, Hungary in 1913, Austria and Argentina in 1919, and Germany and Brazil in 1923. Except for the Scandinavian countries, which adhered to the theory that children should not be tried in courts at all and gave responsibility for delinquent children to child welfare councils, the juvenile court system was gradually adopted throughout most of the world. Treatment of delinquent children was greatly improved by the development of probation services, and all nations gained from the experiences of the Borstal institutions for young offenders established in England in 1908 (*see* BORSTAL SYSTEM). The importance of family life to child development was emphasized by the first mother's pension act passed by the state of Illinois in 1911. (*See* also CHILD WELFARE.)

Perhaps the greatest advances in social welfare during this period were in the area of health and medical care. Medical research developed means to immunize whole populations against major epidemic diseases. Improved medical care and knowledge both decreased infant mortality and increased longevity. Advances in public health removed important obstacles to further urbanization and industrialization. Improved facilities for sewage disposal, water purification, and food preservation diminished the dangers to health inherent in city living. The assumption of responsibility by the state for town and country planning, for standards of housing, and for the provision of recreational facilities all contributed to the health and welfare of industrial communities. (*See* also PUBLIC HEALTH.)

A final example of the change in attitude toward social and economic conditions and individual maladjustment is the growth of the new profession of social work, particularly in the United States and Great Britain. From the "scientific philanthropy" of the Charity Organization societies of the 19th century the knowledge and methods of social work developed to a point where university degrees were awarded for their mastery. By 1930 professional social workers were being called upon in increasing numbers to staff the public social services and to provide the leadership necessary to ensure that services provided would be of the greatest possible assistance to individuals for whom they were designed. (*See* further SOCIAL SERVICE.)

After the 1930s.—The worldwide economic depression of the 1930s and World War II added new dimensions to the concept of social welfare and furthered its acceptance by all classes in the major industrial democratic nations. The trend emerging during the 19th century had been from palliative and punitive measures to the provision of services and financial benefits which would compensate for the failings of the economic and social systems. Emphasis during the postwar period was placed upon the responsibility of the community through voluntary and governmental action to correct such deficiencies.

The Atlantic Charter of 1941 proclaimed the intention of democratic nations to abolish poverty and establish freedom from want. It was realized by all countries that another prolonged depression might lead to the destruction of democracy and submersion of the private enterprise system. In addition, the industrial output and progress during the war that made possible a condition of full employment of all resources served as a challenge to all nations to maintain full employment after hostilities ceased. If full employment could be maintained, freedom from want could be realized, and each nation could establish a "national minimum" standard of living. Increases in productivity accompanying full employment would give to each person a basic income that would supply his essential needs no matter what vicissitudes he experienced.

The ideas of full employment and of a national minimum both received detailed exposition in the Beveridge Report published by the government of Great Britain in 1942. This report gained worldwide attention and was the inspiration for many social welfare developments during the postwar years. Among other matters the report emphasized the importance of family or children's allowances, as it had been determined that about a quarter of all want in Great Britain was due to failure to relate income to the size of family. The influence of the Beveridge Report on western nations is illustrated by the rapid increase in the number of family allowance plans following the publication of the report. Ireland and Canada established universal family allowance plans in 1944, making payments to all children of certain ages regardless of the income of their parents. New Zealand made its plan universal in effect during 1946, and Norway and Sweden instituted such programs in 1946 and 1947 respectively.

The Beveridge Report was able to assume that full employment could be maintained not only because of the wartime record but also because of the "new economics" developed by John Maynard Keynes (*q.v.*) and his disciples throughout the world. Their theories rejected the classical economist's fear of government interference and instead emphasized the positive role which government must play in maintaining full employment and expanding production.

These economists believed that there are many ways in which an economy can be helped by government toward full employment, but all of them must be aimed at encouraging consumption and investment and discouraging excess saving. Because of the emphasis on consumption, social welfare expenditures have come to be considered as instruments of fiscal policy as well as means for the relief of destitution and the improvement of social conditions. Their effectiveness from a fiscal point of view depends upon the extent to which they serve to redistribute income and maintain or increase consumption during periods of threatened economic recession.

An extension of this approach has been the proposal of a "negative income tax," or guaranteed minimum annual income for every individual, as advocated, for example, by Milton Friedman in his *Capitalism and Freedom* (1962), and by Robert Theobald in his *Free Men and Free Markets* (1963). The guaranteed income would assure families of a minimum standard of living (and a minimum level of consumption) regardless of whether wage earners can find jobs. Critics claim such a program would rob people of incentive to work, or find work; proponents say that that objection can be met by regulating the size of income grants. In at least one respect the proposal represents a major departure from established welfare programs in that since it would put money directly in the hands of persons with incomes below the poverty level, it would in many cases replace programs based on categories of need.

It would be impossible to summarize all the social welfare developments since the 1930s; their complexity in any one country defies analysis. Progress has been made by all nations, due to a great extent to increases in productivity and thus in national income. In order to establish freedom from want a nation must be producing sufficient goods and services to provide a basic minimum for all its inhabitants. For underdeveloped nations, therefore, the greatest contribution to overall social welfare has been an increase in investment to increase productivity.

Some appreciation of the range in the proportion of total income devoted to social welfare services can be obtained from studies conducted by the International Labour Office. One of these, published in 1964, attempts a comparison of the total expenditures by various nations during 1960 for compulsory social insurance, certain voluntary insurance schemes, family allowances, special schemes for public employees, public health services, public assistance, and benefits granted to war victims. The percentage of gross national product being expended for these various services was for the United Kingdom 11.1%, for Canada 8.9%, and for Australia 7.9%. In western Europe the percentage for the Federal Republic of Germany was 16.1%, for France 13.9%, for Italy 12.7%, for Sweden 12.4%, and for Denmark 11.1%. The percentage for the United States was 6.3%. To account for these differences it would be necessary to study in detail the social, economic, and political situations in each nation. Decisions regarding the appropriate level of social welfare expenditure are essentially political. Crucial factors affecting such decisions are the total productivity available, the nation's concept of its national minimum, and the relative influence of competing interest groups.

A survey by the U.S. Department of Health, Education, and Welfare showed that in the 1960s more than 100 countries had

some form of social security system in operation. The great majority of more than 75 statutory old-age pension, invalidity, and survivors' benefits programs reported were full insurance measures, but a few still provided pensions subject to a means test. Approximately 30 countries, including all Western European countries except Portugal, had some form of unemployment insurance. In 1964 the Council of Europe prepared a code to promote the development and standardization of social security measures in order to facilitate labour mobility among the member states.

See also WELFARE STATE.

MAJOR TRENDS OF GOVERNMENTAL RESPONSIBILITY

Some idea of the progress made by wealthier nations can be obtained by examining the history and status of social welfare provisions in Great Britain and in the United States as representing the two major trends of governmental responsibility. In Great Britain, the trend has been toward the guarantee of a national minimum social security, with children's allowances, comprehensive health insurance, etc., available to all. In the United States, although there has been extensive development of various forms of social insurance under both public and private auspices, "means test" programs for special categories are usually relied upon to protect the population from dire poverty. For example, the insurance based Medicare provides limited physician and hospital services to eligible aged, while the means test based Medicaid can provide the aged with comprehensive medical care. Under the "War on Poverty" the role of government has been seen as providing opportunities for all to participate fully in the economy (*see* further *The "War on Poverty"* below).

GREAT BRITAIN

Social welfare in Great Britain during the 19th century was characterized on the one hand by the brutal and repressive philosophy of the Poor Law reform of 1834 and on the other by a new reform movement by which the principle of governmental intervention in the interest of the well-being of the people was firmly established. As in most other western nations this progress toward modern social welfare was accomplished first by members of the middle and upper classes who were disturbed by the suffering occasioned by the free operation of the economy. They were joined during the latter part of the century by organized labour and socialists.

Child Labour Regulation.—The movement began with a campaign against child labour. In 1802 Sir Robert Peel secured passage of a bill restricting the employment of pauper apprentices to 12 hours a day between 6 A.M. and 9 P.M. In 1819 Peel was joined by Robert Owen in bringing about the passage of a law forbidding the employment of all children under 9 years and restricting the work of children under 16 years to 12 hours between 5 A.M. and 9 P.M. This act had limited usefulness as it applied only to the cotton industry and no effective means of enforcement were specified. Britain's coalfields also were the scene of important struggles concerning the regulation of working conditions, especially of women and children, and the development of trade unions. The Factory Act of 1833 both restricted child labour and provided for inspection. This protection granted children was the first of a long succession of laws designed to safeguard labour by providing better living and working conditions, by promoting health and sanitation, by developing housing, and by encouraging education. By 1847, for example, the working day for women and all persons under 18 years was limited to ten hours. (*See* also CHILD LABOUR; CHILDREN, LAWS CONCERNING; LABOUR LAW.)

Chartism, Christian Socialism, Fabianism.—Labour's first attempt to gain influence in politics occurred during the decade which ended in 1848 when there were demonstrations and rioting aimed at achieving a people's charter which involved, among other matters, manhood suffrage (*see* CHARTISM). With the collapse of Chartism the workers turned from politics to the improvement of their economic status. In addition to bargaining for higher wages and better working conditions, they developed consumers' cooperatives, stemming from the teachings of Robert Owen. The beginnings of social insurance also were apparent as trade unionism emphasized mutual benefits through insurance against sickness, unemployment, and old age. The improved position of labour resulting from these activities won respect; in 1867 suffrage was granted to urban workers, and in 1874 the first trade unionist entered Parliament.

The defeat of Chartism also brought the socialists to influence; of these the most important groups from the point of view of social welfare were the Christian Socialists and the Fabians. The Christian Socialist movement, started in 1848 by J. M. Ludlow, Frederick Denison Maurice, and Charles Kingsley, emphasized cooperative associations among the workers and education for the working classes. It did much to foster a sympathetic relationship between the church and the socialists and labour leaders. The Fabian Society (*q.v.*) was founded in 1883, and among the nucleus which determined its policies were George Bernard Shaw, Sidney Webb, Sydney Olivier, and Graham Wallas. The Fabians were concerned with immediate and practical reforms which they helped accomplish by issuing scores of publications and by having individual members enter politics and public administration. The far-ranging interests of the society included women's suffrage, an eight-hour day, a minimum wage, housing, public education, and poor relief. (*See* also SOCIALISM.)

Social Investigation.—During the last quarter of the 19th century two other groups had at least indirect effect on England's progress in the field of social welfare. The first was the Charity Organisation Society, founded in 1869 in London by Edward Denison and Octavia Hill and guided for 39 years by its general secretary, Sir Charles Loch. Although the society espoused the principles of the reform of 1834 and opposed all forms of public relief, it did recognize that there were some deserving poor to whom assistance might be given if the purpose of the aid was to preserve the family, strengthen character, and prevent poverty by helping people to be self-supporting. In addition, in the process of social investigation to separate the deserving from the undeserving, much knowledge was gained concerning the living conditions of the poor and their habits. The formal and informal reports of the visitors did much to convince the well-to-do that all poverty was not due to individual irresponsibility and that general social reform was needed.

The second group of social investigators included parliamentary committees, royal commissions, and individuals such as Edwin Chadwick, whose report on sanitary conditions to 1842 set forth facts which showed how environmental conditions contributed to ill health and mortality (*see* CHADWICK, SIR EDWIN). The most influential investigator was Charles Booth (*q.v.*), who undertook in 1886 his study reported in *Life and Labour of the People in London* (1903). He studied people by trades and by the districts in which they lived; he surveyed the conditions under which they worked, the size and quality of their homes. Also examined were hours of labour, rates of pay, and the extent of unemployment and irregular employment. It was a study of all the people, and he found that one-third of the population was on or about the line of poverty or below it. These findings were confirmed for a small city by Benjamin Seebohm Rowntree's study of York (1900), where it was discovered that 28% of the total population was in poverty.

The struggle between uncompromising individualism and the concept of government as a social force continued throughout the 19th century and into the 20th when an attempt to resolve it was made by the Royal Commission on the Poor Laws and Relief of Distress appointed in 1905. The important protagonists were represented on one side by representatives of the Poor Law Division and the Charity Organisation Society, who constituted a majority, and on the other by representatives of the Fabian Society and Socialist-Labour interests. As might have been expected, although there was some fundamental agreement among the commissioners, no single set of conclusions and recommendations was acceptable to all; majority and minority reports were issued. Although the commission's responsibility was to concentrate on the Poor Law, its deliberations and two reports had implications for all of social welfare.

The two reports were in agreement in their rejection of the spirit of the Poor Law reform of 1834. Indicative of this was their insistence that the title public assistance be substituted for that of poor law or poor relief and that the emphasis in administration should be changed from deterrence to help, prevention, and social provision. Both also agreed that there should be a national system of employment exchanges, unemployment and invalidity insurance, and regularization of employment. The crucial difference between the two reports was in their ideas as to the future role of poor relief. The majority report saw the existing functions of the Poor Law carried out by public assistance committees appointed by the county borough councils with treatment and preferred assistance being provided by voluntary aid committees in each community. The minority report, led by Beatrice Webb, wished to do away with the Poor Law entirely and assemble its activities under existing agencies. These old Poor Law functions would be assigned to divisions in the county councils responsible for education, health, pensions, and mental disease, with relief to the able-bodied to be administered by a Ministry of Labour to be created.

Although the recommendations of the commission were not enacted into law immediately as was the case in 1834, they did signify a new attitude toward poverty and social welfare and were soon followed by a rapid extension of social insurance and public assistance outside the Poor Law and finally by the abolition of the Poor Law itself.

Social Legislation, 1906–34.—The general election of January 1906 also provided evidence of a new attitude and was a revelation of the new forces that had been released by the 19th-century enfranchisement of the workers. The Liberal Party received an enormous majority and labour itself had substantial representation. The leadership in Parliament saw government as a means of social change and proceeded rapidly to enact national social welfare measures. The first invasion of the Poor Law came with the Provision of Meals Act of 1906 whereby local education authorities were empowered to supply meals to children unable to take full advantage of education by reason of lack of food. This was followed during 1907 by the Education (Administrative Provisions) Act, which provided for medical inspection and attention to the health and physical condition of schoolchildren. In 1908 came the Old Age Pensions Act, which provided a flat weekly benefit to all those over 70 years whose income was below a certain amount and who, until 1919, were considered to be "deserving." Also in 1908 the Coal Mines Regulation Act established the principle of the eight-hour day. In 1909 the Labour Exchanges Act created a system of labour exchanges designed to attack unemployment by increasing the mobility of labour, and the Trade Boards Act made a beginning at setting minimum wages.

The culmination of this period of social legislation came with the National Insurance Act of 1911, which provided for compulsory health and unemployment insurance for certain industrial workers. Leadership in sponsoring this program was provided by David Lloyd George. The intention of the government to adopt the principle of compulsory insurance was announced by Winston Churchill, and the details were worked out by Sir Hubert Smith in collaboration with William Henry (later Lord) Beveridge. Both the health and unemployment plans were to be financed by contributions from employers, employees, and the state, setting a precedent to be followed by future social insurance programs in Great Britain. Participation in the insurance was limited to manual labourers and to persons in other occupations receiving less than a prescribed amount of wages. Health insurance was administered through approved nonprofit groups organized by friendly societies (*see* FRATERNAL ORGANIZATION) or labour unions or as adjuncts of commercial insurance companies. Unemployment insurance was administered through a national system of employment exchanges. In 1925 the principle of insurance was extended to cover the eventualities of old age and death by the Widows', Orphans' and Old Age Contributory Pensions Act of that year.

The social legislation beginning in 1906 made it possible for many more persons to avoid applying for poor relief when their earnings were interrupted but did nothing to alter the structure of the Poor Law itself. In 1918, however, some of the harshness was reduced by the removal of the disenfranchisement provisions. In 1919 responsibility for national supervision was placed in the newly created Ministry of Health, and in 1929 the local boards of guardians were abolished and their functions turned over to the county councils. By 1930 the tenets of 1834 had been discarded to the extent that aid was regularly being given to the able-bodied unemployed in his own home. This change in philosophy of Poor Law administration can be attributed, in part at least to the failure of unemployment insurance to meet the need occasioned by the widespread unemployment which followed World War I and continued into the 1930s. Those forced to apply for relief as a result of the decrease in the number of jobs available could hardly be held personally responsible for their plight.

By 1931 the unemployment insurance plan had ceased to have any actuarial basis and the fund had long been insolvent. This situation had been caused by successive extensions of the period of benefits and the payment of "uncovenanted" benefits which assumed that contributions would follow when employment was obtained. The National Economy Act of that year put the scheme back on an actuarial basis by increasing contributions and decreasing benefits, and a system of transitional benefits from national funds was instituted for those no longer eligible. Need for these payments was determined by county public assistance committees who also administered poor relief. Although it was required that these allowances be in cash and that no work test be imposed, there was great dissatisfaction with the plan because of the great variation in amounts paid from county to county from national funds. A centralized national administration of public assistance to the unemployed was finally established by the Unemployment Act of 1934 which created the Unemployment Assistance Board. Allowances set on a national basis were administered by national civil servants whose decisions were subject to review by local appeal tribunals. War-related responsibilities as well as supplementation of pensions and insurance benefits were assumed by the agency, which in 1940 became the Assistance Board.

Post-World War II Legislation.—By the beginning of World War II in 1939 Britain had a fairly comprehensive public social welfare system. There were public medical services, a national health and unemployment insurance system, widows' and orphans' pensions, old-age pensions, public assistance, and provision for the control and subsidization of housing and the supervision of town planning. These were supplemented by an extensive network of voluntary services. Wartime experience, however, emphasized that there were serious gaps and weaknesses in the existing system. The problems of evacuation, for example, showed that there were considerable inequalities between some of the medical services provided in the towns and in the country.

The aspirations of the people of Britain for a better and more economically secure life after the war were given official expression in 1942 in the Beveridge Report on *Social Insurance and Allied Services*. It recommended the extension of social insurance so that a true national minimum and "cradle to the grave" social security would be available to all no matter what exigencies might occur This interdepartmental report signed by Beveridge insisted, however, that this plan would be successful only if there was a system of children's allowances, if there were comprehensive health and rehabilitation services for all, and if mass unemployment could be avoided.

With the end of World War II, Britain's public social welfare services were reorganized and enlarged to form such a comprehensive system. A series of acts forms the framework within which this system continues to develop. The Family Allowances Act, 1945, the National Insurance Act, 1946, and the National Insurance (Industrial Injuries) Act, 1946, were all based on the Beveridge Report. The National Health Service Act, 1946, established the machinery for operating the new health services, while the New Towns Act, 1946, and the Town and Country Planning Act, 1947, created the conditions necessary for rebuilding the nation in a rational and orderly way. The National Assistance Act of 1948 removed the last traces of the old Poor Law by providing that anyone in need should be assisted out of central government

funds, while the Children Act of 1948 provided for a more nearly equal chance in life for the child deprived of normal parental care.

With the Poor Law specifically repealed in 1948, the only qualification for public assistance is need according to standards provided in regulations which are subject to parliamentary approval and are revised from time to time according to cost of living trends. The amount of grant payable is determined by comparing any resources already available to the applicant with the figure at which his needs are assessed according to regulations. The figures are subject to addition for rent according to the amount paid and may be altered when particular circumstances so require. The provision of welfare services under the act, as distinct from financial aid, is the responsibility of the local authorities.

Child welfare services are also the responsibility of the local authorities and their cost is shared by the localities and the exchequer. By the Act of 1948 it is the duty of the local authorities to receive into their care any child under the age of 17 who appears to them to have no parent or guardian, or who has been abandoned, or whose parents are unable to provide for him temporarily or permanently. They must also accept children committed to them by the juvenile court or under the Matrimonial Proceedings Act in exceptional cases resulting from divorce. Children in care are, if possible, boarded out with foster parents or may be placed in a children's home managed by a local authority or a voluntary organization. The children's officer of each locality is assisted by a staff of social workers who undertake inquiries, give help and advice in planning for the care and upbringing of individual children, and supervise them in foster homes.

The development of comprehensive public social services in Great Britain has not deprived the voluntary agencies of a useful role in social welfare. They complement the statutory services and can often undertake work outside the scope of national and local agencies. They are aided by public funds, and in many branches of social service they act as agents of the public authorities. The larger societies concerned with children are Dr. Barnardo's Homes, the Church of England Children's Society, and the Catholic Child Welfare Council, all members of the National Council of Associated Children's Homes. Valuable community service is still rendered by the 50 or so social settlements found in the poorer districts of the cities. In all large and many small towns there are Citizens' Advice bureaus. The Family Welfare Association, successor to the Charity Organisation Society, receives in its area offices in London applications for help from over 4,000 families and individuals a year. About 180 other welfare agencies help families in difficulty or distress, marriage guidance is given in over 100 centres, and the Family Planning Association maintains about 200 clinics. Welfare services for the sick continue to be provided by the British Red Cross Society, the Order of the Hospital of St. John, St. Andrew's Ambulance Association, and many others.

The United States

The history of social welfare in the United States cannot be traced in as orderly a fashion as that of Great Britain. In the United States social welfare functions have traditionally been considered as being exclusively within the sphere of the state governments with financial and administrative responsibility devolving to counties, townships, and municipalities; until the 1930s there were only isolated instances of federal concern. The status of social welfare at any particular time, therefore, must be described in general terms, since each state developed its provisions at a pace which reflected its needs, the status of its industrialization, and the attitudes of politically dominant groups toward social welfare and particularly toward poor relief. Any consistency results from the fact that as each state enacted social welfare programs it benefited from the experience of those which preceded it. In addition, it is difficult to assess the influence of interest groups and changing economic and social philosophies. In both state and federal governments dissatisfactions tend to be met by changes in policy by one or both major political parties rather than to be expressed in a separate political movement. The influence of organized labour on social welfare, for example, is difficult to appraise. Prior to the 1930s it was the avowed policy of the American Federation of Labor to concentrate on collective bargaining and not to sponsor remedial social legislation. With the formation of the Committee for Industrial Organization (later called Congress of Industrial Organizations) and a change in leadership of the A.F. of L. the labour movement began to assume a positive political role and exerted a powerful influence on public policy, but always within the framework of the two-party system.

Early History.—The early colonists had brought with them from England the methods of the Poor Law of the 17th century with its emphasis on local responsibility and administration. Because of the necessity for individual initiative and hard work in developing and expanding a new country, harsh attitudes toward those unable to support themselves were common and the settlement laws designed to protect localities from being burdened by paupers from some other place were stringently enforced (*see* Poor Law: *United States*). As in England at the time, persons who were dependent because of physical and mental disabilities were treated no differently than those unemployed because of some other factor. By the beginning of the 19th century the general attitude toward the poor and toward public relief became even more punitive as the ideas of the Enlightenment had their effect and as legislation in the United States reflected experiences in England leading to the reform of 1834. Increasingly the almshouse was considered the most suitable and economical method of caring for those in need. Many states made county or township almshouse care mandatory.

The reforming and humanitarian zeal typical of the middle classes of this period was concentrated on the abolition of slavery and the struggle for free public education. Some attention, however, was paid to the problems of poverty. In 1841 Robert M. Hartley founded the New York Association for Improving the Condition of the Poor, to save the "deserving" poor from the almshouse and to emphasize moral aid rather than material relief. In 1853 Charles Loring Brace founded the New York Children's Aid Society, a pioneer agency in removing children from the almshouses and orphanages and placing them in foster homes. During this period beginnings were also made for separate provision for special classes of dependents under state government auspices. A school for the "deaf and dumb" was established in Connecticut in 1816 and another in Kentucky in 1822, both of which received some federal aid. In 1841 Dorothea Lynde Dix (*q.v.*) began her crusade for the improvement of the treatment of the insane. She carried her cause personally to every state east of the Rocky Mountains, and in almost every instance her memorial to the state legislature was followed by the erection of a state hospital or the improvement of an existing one. Her memorial to the Congress finally resulted in passage of a bill which would have granted public lands to the states for the care of the insane. The bill was vetoed by President Pierce on the basis that it would establish the principle of federal responsibility for "all the poor in all the states." This veto was used as a precedent for denying aid to the states for social welfare until the 1930s.

Social Reforms to World War I.—The period between the Civil War and the opening of the 20th century was one of rapid industrialization characterized by ruthless and predatory business practices. Although evidence of social deterioration, such as the growth of slums and the poverty of immigrant and native workers, did not go entirely unnoticed, all could be explained by the theories of *laissez faire* and Social Darwinism. Some attempts at improving conditions, however, were made by three groups. First there were the state boards of charity and corrections. By 1867, 16 of the 36 states had established such boards following Massachusetts' example of 1863. Their responsibilities were initially limited to inspection and supervision but later included the direct administration of prisons, reformatories, mental hospitals, and other state welfare institutions. The second group comprised the Charity Organization societies which were found in 92 cities by 1877. Their philosophy and methods were similar to those of the London Charity Organisation Society, with emphasis on individual treatment of deserving applicants for aid and opposition to all forms of public relief. Their "scientific philanthropy" developed over the years into modern social work and its principal method, case-

work. Third were the social settlements (*q.v.*) the first of which was established in New York City in 1886. Perhaps the most important from the point of view of social welfare reform was Hull House founded in Chicago by Jane Addams in 1889, since the group assembled there were outspoken in their belief that government has a responsibility for the well-being of all the people.

While Great Britain was embarking on its great period of social legislation beginning in 1906, the United States was in the midst of the Populist revolt and the Progressive Party movement, which began in the 1890s and continued until World War I. Primary emphasis during this period was on reform of state and local government and the control of business, but progress in social welfare was also made. After overcoming constitutional difficulties in 1908, for example, reformers began the process of achieving state laws on industrial accidents, occupational diseases, factory inspection and safety measures, regulation of child labour, and special provisions to protect women in industry. Attempts to achieve a national child labour law were twice defeated by adverse Supreme Court decisions; not until 1938 were they successful. In 1909 Pres. Theodore Roosevelt called the first White House Conference on Children, which emphasized the importance of the family and the home and one result of which was the establishment in 1912 of the U.S. Children's Bureau. Among the most important of the new social welfare programs enacted during this period of economic, political, and social reform were workmen's compensation, mothers' aid, and pensions for the blind. The first established the principle of social insurance in the United States and the others achieved the first breakup of the poor laws.

In 1908 a federal Compensation Act covering civil employees of the federal government provided a stimulus to the states to enact workmen's compensation laws. The first law to be held constitutional by the state courts was passed in 1911, and by 1920 workmen's compensation laws were in effect in 43 states, Alaska, and Hawaii. The White House Conference had encouraged concern for the welfare of children left orphaned or abandoned or taken from poverty-stricken parents and so laid the groundwork for the development of mothers' aid legislation. The first statewide mothers' pension law was enacted in Illinois in 1911, and 17 states had followed its example by 1913. The needs of the blind also gained early recognition, the first special pensions being provided by Ohio in 1898 and by Illinois in 1903.

Other important social welfare developments during this period included the expansion of public parks and playgrounds and the establishment of voluntary recreational agencies; the growth of state and local public health departments and the improvement of public health services; the strengthening of child welfare services and the spread of the juvenile court idea; and the rise of philanthropic foundations devoted to social welfare such as those of Carnegie, Rockefeller, and Russell Sage (*see* FOUNDATIONS, PHILANTHROPIC). Finally there was the development of Community Chests and Councils of America to coordinate the financing and activities of the many social welfare agencies by then found in all population centres.

The 1920s.—The social reform movement which halted during World War I did not resume following the Armistice until the economic depression of the 1930s. During this period of relative complacency, however, some advances were made. In 1920 the federal government offered grants-in-aid for the vocational rehabilitation of disabled persons. The following year funds were provided the states to help support maternal and child health services. All but three states were receiving grants under this program when it was discontinued in 1927. Further breakup of the Poor Law occurred when Montana and Nevada passed old-age assistance laws in 1923. By the end of 1929, 11 states had such provisions.

The 1930s.—The depression of the 1930s found the social welfare provisions of the United States wholly inadequate to cope with the needs of the millions of unemployed men and women. Except for the few categories already mentioned, poor relief was almost entirely locally administered and locally financed. The rapid increase in relief loads during 1930 and 1931 placed an impossible burden on local, and particularly municipal, finances. The first shift in responsibility was to the states. New York was the first to establish a temporary relief administration and was followed by seven states prior to May 1932. In that month Congress passed the Federal Emergency Relief and Construction Act marking the beginning of federal responsibility, which offered emergency loans to the states to help meet the costs of relief. Only six states did not take advantage of the offer.

Franklin D. Roosevelt's inauguration as president in March 1933 marked the beginning of a new era. On the basis of the countrywide support he received in 1932 and 1936 he was able to insist upon the enactment of a wide assortment of social welfare legislation. Important in this regard was the backing he received from the now politically articulate labour movement.

The first measure enacted to relieve the plight of the unemployed established the Civilian Conservation Corps (March 1933 to July 1942), which provided work-camp employment to over 3,000,000 young, unmarried men during the ten-year period. In May 1933 the Federal Emergency Relief Administration was established and given authority to make grants to the states for both work relief and direct relief. The administration was created for two years and all powers were to be exercised by the administrator, Harry L. Hopkins. This program lasted until the autumn of 1935 and expended a total of $3,000,000,000. The FERA exerted a lasting influence on the administration of public assistance, particularly through its requirement that public funds must be administered by public agencies and its encouragement of relief payments in cash rather than in kind. Between November 1933 and March 1934 the FERA was temporarily discontinued and replaced by the Federal Civil Works Administration, which was a gigantic federal works agency offering to pay wages to 4,000,000 unemployed if state and local governments would put them to work. Other social welfare programs enacted by Congress prior to 1935 were the Public Works Administration (1933–42) which aimed at stimulating the economy with large-scale construction projects, the U.S. Employment Service (1933), and the Federal Surplus Commodities Corporation (1933—later called Surplus Marketing Administration), which purchased farm surpluses and distributed them to public assistance agencies.

When the FERA was discontinued it was replaced by the Works Progress (later Work Projects) Administration (1935–42), designed to give work to all needy persons who could work and to return responsibility for the "unemployables" to the states. The National Youth Administration (1935–42), first a part of the WPA and later an independent agency, provided part-time employment for needy school and university students and others, helped establish job training and counseling programs, and encouraged the development of constructive leisure-time activities for youth.

In June 1934 President Roosevelt set up a special cabinet committee on economic security, to make recommendations concerning a comprehensive program relating to old-age security and unemployment, sickness, and health insurance. A report of the committee was transmitted to Congress on Jan. 17, 1935. The resulting Social Security Act, which became law on Aug. 14, 1935, marked a new stage in the acceptance by the federal government of responsibility for the welfare of all citizens. It established a national contributory old-age retirement annuity system for workers in industry and commerce and laid the basis for a nationwide system of insurance to protect persons against the risks of short-term unemployment. In addition it provided for federal grants-in-aid to the states for old-age assistance, aid to the blind and to dependent children, and for maternal and child health services, child welfare services, services for crippled children, and vocational rehabilitation.

Since 1935 most important social welfare developments have been extensions or improvements of the Social Security Act. Three later federal acts, however, must be mentioned. The Fair Labor Standards Act of 1938 prescribes national standards for wages, hours, working conditions, and child labour applicable to firms producing goods destined for interstate commerce. In 1946 Congress passed the Employment Act, which declares that it is the continuing policy and responsibility of the federal government to promote maximum employment, production, and purchasing power. The National Mental Health Act (1946), designed to provide a method

for financing research and training programs and to assist the states in establishing community mental health centres, was followed in 1963 by the Mental Retardation and Community Mental Health Centers Act that made available funds to the states for the construction of community facilities. Two other federal measures not related to the Social Security Act but which have been important social welfare developments were the Manpower Development and Training Act of 1962 and the Economic Opportunity Act of 1964. Both of these are described below.

Social Insurance.—By 1966 the limited old-age benefits of the Social Security Act of 1935 had become the Old Age, Survivors, Disability and Health Insurance Program. The health insurance or Medicare feature was added in 1965. It provided for hospital, nursing home, and home nursing care for the elderly, plus a voluntary medical insurance plan to help pay the cost of physician's services including surgery whether rendered in a hospital, clinic, doctor's office, or private home. (*See* further *Medical Care* below.) Coverage of the old age, survivors, and disability insurance programs had been successively extended until in the 1960s nine out of ten workers were included. Since 1950 Congress has regularly revised the benefit schedule to reflect changes in the cost of living.

Unemployment insurance, adopted by all states shortly after the passage of the Social Security Act, underwent little change during the ensuing years and in some aspects regressed. Coverage remained as limited as in 1935 except that in 1954 it was extended from employers of eight or more persons to employers of four or more. No standards as to amount and duration of benefits had been imposed by the federal government, and benefits stated as a percentage of average wages had generally decreased since the program was introduced.

Workmen's compensation had remained since its beginnings in the early 1900s a state-controlled program providing benefits and medical care to persons injured, and benefits to survivors of those deceased, in the course of employment. Because of the complete lack of centralized supervision and standard setting, there was a confusing array of coverage provisions, benefit levels, and administrative arrangements.

Public Assistance.—Despite the extension of social insurance, about 4 persons out of every 100 in the population were dependent upon some form of public assistance during the 1960s. They were in need and either ineligible for benefits provided by other public programs or, if eligible, received insufficient amounts. This assistance was provided by the states and localities with the help of the federal government under the three categories of the Social Security Act of 1935, a fourth category, aid to the permanently and totally disabled, established in 1950, and Medicaid, introduced in 1966. Those in need but not eligible for any of the federally aided programs depended upon general assistance or poor relief, which in most states was still locally administered and financed.

All 50 states had programs of old-age assistance which provided aid to persons over age 65 who were in need, aid to dependent children which assisted needy families with children who had lost support or care because of a parent's death, incapacity, or absence from the home, and aid to the blind. Aid to families with dependent children was also provided by 18 states to families where loss of support was due to the unemployment of a parent. All but one state had legislation providing aid to the permanently and totally disabled. Financial participation by the federal government in the case of each of these programs was computed as a percentage of the average grant paid by each state up to a specified maximum. Since 1958 this percentage has varied to some extent in accordance with differences in per capita income among the states.

Federally aided public assistance is superior to poor relief primarily because of the requirements state programs must fulfill in order to be eligible for grants-in-aid. These requirements are aimed at protecting the needy person's right to public assistance if he is eligible according to standards set by the state. For example, assistance must be available in all subdivisions of the state, all persons must have an opportunity to apply for assistance and have their applications acted upon within a reasonable time, and an opportunity for a fair hearing before the state agency must be provided anyone whose claim is not acted upon within a reasonable time. The federal government also requires that assistance be given in the form of money or medical care. This provision has been interpreted as preventing any restriction on the recipient's use of the money payment. He may spend it as do others in the community and continue to live in his own home without interruption of family life. In 1956 Congress declared that a major purpose of public assistance administration was to promote the well-being of the nation by encouraging the states to place greater emphasis on helping to strengthen family life and helping needy families and individuals attain the maximum economic and personal independence of which they are capable. The 1962 amendments to the Social Security Act affirmed this intent by offering additional funds to the states that provide public assistance recipients with prescribed social services.

The federal government in its requirements sets no standards as to what constitutes a national minimum for health and decency. Each state, therefore, is responsible for determining who are needy people and how much they will receive under a given program. States differ both in their definition of need and the degree to which they decide to meet need as determined. One state may provide for some medical needs in its old-age assistance program, but not for its aid to dependent children program, while another state may make no provision whatsoever for medical care. In 1966 average payments per recipient for old-age assistance, for example, ranged from a low of $40 per month in Mississippi to more than $123 in Wisconsin. States not only differ in the amounts of assistance they are able or willing to pay but also in their definitions of what resources an applicant may retain and still be eligible. Policies vary greatly, therefore, with respect to the responsibility of relatives, the value of life insurance, cash reserves, and the ownership of real property.

The federal government also permits the states to require a certain period of residence in the state before an individual can be eligible for aid. Such provisions, reminiscent of the settlement provisions of the old Poor Law, occurred in the legislation in almost all of the states. For old-age assistance, however, less than half the states required as long a period as the Social Security Act permits; *i.e.*, five of the last nine years. The common residence requirement for aid to dependent children was one year.

Those needy individuals and families who cannot qualify for one of the federally aided categories of public assistance must resort to general assistance, which is administered in most states on a local basis in much the same manner as the Poor Law of the 19th century. Such aid is usually given in cash but frequently in the form of orders for groceries, rent, and other items. In most states it is provided only to unemployable persons, and nonresidents are aided only in emergencies with arrangements being made for their return to their state of residence as quickly as possible.

The "War on Poverty."—During the early 1960's public concern was directed to the large number of families living in poverty despite the economic prosperity of the nation as a whole. Resulting social welfare policy emphasized the need of persons in poverty for education, training, work experience, and social services rather than direct measures of income redistribution. The 1962 Public Welfare Amendments to the Social Security Act provided the states with funds to finance such services for public assistance recipients. In the same year Congress passed the Manpower Development and Training Act by which funds were made available for the costs of tuition and subsistence for persons requiring vocational training or retraining. The Economic Opportunity Act (1964) had two principal aims. One was to relieve the plight of young people unable for various reasons to qualify for jobs available in an expanding and technologically oriented economy. For this purpose the Jobs Corps provided education and training in residential centres, and the Neighborhood Youth Corps offered work experience to youths within their own communities. Most far-reaching, perhaps, was the Community Action Program which provided funds to local groups attempting to relieve some of the causes of poverty and deprivation. Although each locality determined the nature of the program to be supported, "Operation

Headstart" providing preschool youngsters from disadvantaged homes cultural and educational experiences to prepare them for school attracted the greatest measure of public interest and support. Most innovative in its approach to poverty was the demand that the poor themselves have a voice in determining the policies of community action programs. (*See* also POVERTY.)

Medical Care.—The growth of publicly supported general medical care has been very slow in the United States. Until 1965, protection against the costs of illness, although widespread, was available only through private contractors. The movement for compulsory state-supported health insurance which began during the early years of the 20th century did not achieve any success until 1965. In that year Medicare was established under Social Security which benefited persons aged 65 and over, and met part of the costs of hospital and home nursing care. A voluntary medical insurance plan, with the federal government matching the premium of the insured, was also instituted to help pay the costs of physician's services. More important in terms of possible future impact were the provisions for Medicaid also enacted in 1965. That program, administered by state public assistance and health agencies, permits greatly expanded hospital and physician's services to those considered unable to afford such care from their regular income, whether or not they are eligible for other forms of public assistance. The federal government contributes generously to all expenditures made by the states if certain minimum requirements are fulfilled. The potential of this program to provide free comprehensive medical care is illustrated by the state of New York where a family of four persons with an income of less than $6,000 per year is eligible for completely free comprehensive hospital and physician services. Most protection against the costs of illness is provided by voluntary plans contracted for by individuals or by employers for their workers. (*See* also HEALTH INSURANCE; MEDICAL CARE, GOVERNMENT; SOCIAL SECURITY.)

Voluntary Programs.—Private social welfare agencies continue to fulfill an important function despite the expansion of governmental programs. Their services are so numerous and so varied as to make summarization impossible. In a typical urban community will be found both sectarian and nonsectarian family service agencies, child welfare agencies, mental health clinics, home nursing services, medical out-patient clinics, and a variety of recreation and group work agencies. Certain national agencies such as the American Red Cross and the National Traveler's Aid Association also have branches in many localities. The financial support for these agencies is for the most part obtained by private donations although public subsidy of private child welfare agencies and mental health clinics is common. Fund raising for local agencies and local branches of some national agencies is usually accomplished through a federated appeal. In most communities the coordination of services is the responsibility of a council of social agencies or health and welfare council to which most public and private agencies belong.

INTERNATIONAL SOCIAL WELFARE

International social welfare programs have increased and expanded with the growing realization that the development of human resources is the real key to a better way of life for the peoples of all countries and that relieving poverty, ill health, and misery is an important part of the task of maintaining peace. The focus of such activity is in the United Nations, where the Department of Economic and Social Affairs of the UN Secretariat administers a worldwide program of research, technical assistance, community development, and information. The principal organ of the United Nations in the social field is the Economic and Social Council. Policy recommendations for this group are developed by the UN Social Commission and carried out by the Bureau of Social Affairs and Advisory Welfare Services.

Other social welfare activities are carried on by specialized agencies which have been established by intergovernmental agreement and are coordinated by the UN Economic and Social Council. The World Health Organization (WHO) helps combat disease and epidemics throughout the world. The United Nations Educational, Scientific and Cultural Organization (UNESCO) assists governments to eradicate illiteracy. The Food and Agriculture Organization of the United Nations (FAO) seeks, among other things, to overcome chronic food shortages. The UN High Commissioner for Refugees supervises the application of the international convention relating to the status of refugees. The oldest of the specialized agencies is the International Labour Organization (ILO) which gives special attention to problems of income security and labour legislation.

SOCIETY OF JESUS: *see* JESUS, SOCIETY OF.

SOCINUS, the latinized form of the Italian Sozini, Sozzini, or Soccini, the name of two Italian religious thinkers of the 16th century, whose influence survived in Socinianism and subsequently in Unitarianism (*q.v.*).

LAELIUS SOCINUS (Lelio Francesco Maria Sozini) (1525–1562) was born at Siena on March 25, 1525, of a distinguished family of jurists. He himself was trained for the law at Padua, but his desire to trace the laws of men to their source in the law of God led him to biblical research and this led him to doubt the dogmas of the church. At the age of 21 he went to Venice, then the leading city of the reformist movement within the church, and afterward traveled extensively in Switzerland, France, England, and Holland, his family name and personal charm assuring him a warm welcome. At this stage he combined enthusiastic piety with subtle theological speculation. At the end of 1548 he settled for a time in Zürich where he pursued his studies in Hebrew and Greek. During the following year he was in constant correspondence with Calvin on doctrinal questions. In 1550 he was Philipp Melanchthon's guest in Wittenberg. Wherever he went he prosecuted his theological inquiries, being particularly concerned with such questions as the resurrection of the body, grace and predestination, the sacraments, the doctrinal basis of the original gospel, and repentance. The fate of Michael Servetus (*q.v.*) directed his mind to the Trinity. Rumours that he was a heretic began to spread, and after a warning from Heinrich Bullinger he composed a confession of faith (July 1555), which, while giving the impression of orthodoxy, yet left the door open to heretical views.

In 1556 the death of his father, who had disinherited him, and the sequestration of his share of his father's estate by the Inquisition left Laelius in financial difficulties. Though he secured diplomatic support from the courts of Vienna and Cracow, he

failed to recover his patrimony. He spent the last years of his life at Zürich and died there on May 14, 1562.

His confession of faith, letters, and two dissertations are his only extant writings. He was too speculative a thinker to reach any well-defined conclusions, but his work undoubtedly bore fruit in the fully developed system of his nephew, Faustus.

FAUSTUS SOCINUS (Fausto Paolo Sozzini) (1539–1604) was born at Siena on Dec. 5, 1539, the second child of Alessandro Sozzini (1509–41), brother of Laelius. He was brought up by his mother and grandmother and had no systematic education. Early in 1561 he went to Lyons, possibly for study. After a visit to Zürich to acquire his uncle Laelius' papers (1562), he was briefly in Geneva. On returning to Lyons, he composed his first work, an interpretation of the prologue of St. John's Gospel, in which he wrote of Christ as divine by office rather than by nature.

Toward the end of 1563 he went back to Italy and became secretary to Duke Paolo Giordano Orsini, son-in-law of Cosimo I de' Medici, ruler of Florence. He afterward regarded this period spent at the Florentine court, where he lived in outward conformity to the Catholic Church, as 12 wasted years, though he wrote there (1570) *De sacrae scripturae auctoritate*, in which he established the authority of Scripture on rational and historical grounds. After the death of Cosimo I (1574), Faustus settled for more than three years at Basel, studying Scripture. As a result of discussion with the French Protestant minister Jacques Couet (Covetus) on the question of salvation through Christ, he wrote *De Jesu Christo servatore* (completed 1578, published 1594 in Cracow), in which he denied that Christ appeased the wrath of God by suffering the penalty, through his death, that was justly due to man. Socinus taught that the Word or will of God appeared in the form of flesh, as a man. The resurrection of Christ enables his devout followers likewise to look forward to resurrection in spiritual bodies. After the resurrection, Christ ascended to the right hand of God and henceforth shared God's power. Thus Christ, though purely human in nature, was worthy of adoration as the adopted Son of God, on whom, after the ascension, God had bestowed the government of the world.

The circulation of this work in manuscript brought him to the notice of Giorgio Blandrata (*q.v.*), then court physician in Transylvania, where an eloquent Unitarian bishop, Francis Dávid, had renounced the worship of Christ. Blandrata, fearing that this step would jeopardize the religious settlement reached earlier (*see* TRANSYLVANIA), invited Socinus to visit Kolozsvár (modern Cluj, in Rumania) to persuade Dávid to accept his own doctrine of a modified invocation of Christ within a Unitarian theological scheme. Socinus' reasoning, however, was unsuccessful (autumn 1578–spring 1579).. After leaving Transylvania, Socinus went to Cracow, where he attained a predominant influence in the Minor (or antitrinitarian) church centred on the colony at Rakow. He became its accepted leader and eventually set his stamp upon its theology, although his views on baptism, which he regarded as applicable only to converts to Christianity, apparently excluded him from formal membership. He converted the Arians of Little Poland from their avowal of Christ's preexistence and persuaded most of the Lithuanian Unitarians, at a provincial synod, to accept his teaching that Christ might be invoked in prayer.

The controlling interest in the teaching of Socinus was the attainment of eternal life. The Christian religion was a divinely revealed way of attaining that life, which man, who is by nature mortal, learns through Scripture. Jesus Christ was in his nature a real man though not an ordinary man, for he was conceived by the Holy Spirit. He lived without sin and by his suffering taught men how to bear their own sufferings. The Lord's Supper is an act commemorating the death of Christ; faith is not merely belief that the teaching of Christ is true but such belief as issues in repentance for sins and in an obedience which leads to eternal life.

Socinus supported the Anabaptist Rakovians in their refusal to bear arms and held that the command not to kill admitted no exceptions. Men must, however, offer obedience to the civil government where this did not conflict with the teaching of Christ, and members of the church could act as magistrates if not required to inflict capital punishment.

To avoid persecution Socinus left Cracow in 1583 to live on the nearby estate of the nobleman Krzysztof Morsztyn, whose daughter Elzbieta he married in October 1586. Her death the following September and the later loss of his property through the action of the Inquisition at Siena (1590) were severe blows to Socinus. From 1587 to 1598 he lived in Cracow supported financially by his friends. In 1598 enraged university students attempted to martyr him, and he took refuge at Luslawice, a village east of Cracow. At the turn of the century he began to collect and revise his writings for publication, but the project was unfinished when he died on March 3, 1604, at Luslawice. His incomplete *Christianae religionis institutio* may well have been the basis for the Rakovian catechism, a full exposition of Socinian thought published at Rakow in 1605.

The importation of Socinian writings into England during the 17th century, while not the primary source of antitrinitarian thought there, was long influential upon the development of Unitarian theology, particularly in the doctrines of the person and work of Christ.

SOCIOLOGY (ARTICLES ON). Sociology as an academic discipline represents one approach to the systematic study of man and society in order to understand and, ultimately, to attempt to help determine the course of civilization and culture. The broad background of this study is discussed in CIVILIZATION AND CULTURE and, more specifically, in SOCIAL SCIENCES. The article SOCIOLOGY traces the history of its development as a science and discusses fields of specialized interest, and sociological theory, methods, and applications. As a discipline, sociology represents a way of looking at and trying to isolate and analyze significant aspects (problems) of society in order to understand them, find out what causes them, and try to modify or control them. One such problem area is outlined under POVERTY and UNEMPLOYMENT. The history and philosophy of efforts to deal with the problem are covered in PHILANTHROPY; POOR LAW; and WELFARE STATE. Programs to combat poverty are dealt with in CHILD WELFARE; SOCIAL SECURITY; SOCIAL WELFARE; UNEMPLOYMENT INSURANCE; and DISASTER RELIEF. Techniques are covered in SOCIAL SERVICE, while a number of shorter articles describe specific institutions and social inventions, as BEDLAM; CASUAL WARD; CHARITY COMMISSIONERS FOR ENGLAND AND WALES; FOUNDLING HOSPITAL; RED CROSS; and SOCIAL SETTLEMENTS.

Another problem area is that of crime and delinquency (*see* CRIME; JUVENILE DELINQUENCY). CRIMINOLOGY presents a survey of theories of causation, correction, and prevention; programs and institutions are covered in PRISON; PROBATION; PAROLE; RECIDIVISM; and HABITUAL OFFENDERS; and, for youthful offenders, REFORMATORY and the British BORSTAL SYSTEM. (*See* also CHILDREN'S COURT.)

Problems of urbanization are dealt with in CITY; METROPOLITAN AREA; HOUSING; and URBAN RENEWAL. (*See* also GARDEN CITY; NEW TOWNS.) Population problems are the subject of POPULATION; BIRTH CONTROL; and MIGRATION. (For population data *see* VITAL STATISTICS.)

Inter-group relations are the concern of CLASS, SOCIAL; SEGREGATION, RACIAL; GENOCIDE; GHETTO; MARGINAL GROUPS, and related articles. CHILD LABOUR; FORCED LABOUR; PROSTITUTION; and SLAVERY deal with the exploitation of others.

Sociology shares with other social sciences concern with man's most universal institution, the family, its history, and the changes it is undergoing in the modern world: these are analyzed in MARRIAGE and FAMILY.

Other articles of general interest include COMMUNICATION;

INVENTIONS AND DISCOVERIES; and SECRET SOCIETIES. Sociology also deals with a number of subjects which have a narrower or more specialized historic or modern interest, such as CONCUBINAGE; and NUDISM.

Each of the above references will refer the reader to related articles. Biographies of the leading personalities in each field indicate their contributions.

SOCIOLOGY is one of the several specialized social sciences. Its primary objective is to gain a knowledge of man and society insofar as it may be achieved through investigation of the elements, processes, antecedents and consequences which are involved in group living.

Sociology is differentiated from the other social sciences primarily by the basic fact with which it starts, the fundamental assumption which underlies its activities, and the problems with which it is concerned. The basic fact is the relative helplessness of the human infant at birth who is always born into, and depends for his survival upon, a social group. The fundamental assumption is that the conduct of the person—his ways of thinking and ways of acting—and the nature of the social orders—its structure, function, and values—are to be understood as a product of group life. The problems with which sociology is concerned may be stated as a long list of specific items but, more appropriately, may be generalized into broad groupings of subject matter such as those represented by social organization, social psychology, human ecology, and demography. Each one of these broad fields of sociology may be further divided into subfields and into rural and urban aspects, and all are concerned with various problems of theory and method.

As a social science, sociology, contrary to popular misconception justified in part by its early history, does not have as its objectives the determination or modification of social values, the proposal of reforms, the design or administration of welfare programs, or the direct promotion of a better social order. These are important objectives to be sure, but they are the tasks of the statesman, the administrator, the legislator, the educator, the social worker, the clergyman, the labour leader, the agitator, and the propagandist, rather than of the sociologist as a social scientist. The discipline of sociology, strictly speaking, is concerned only with the pursuit and funding of knowledge about man and society. In such knowledge, which ideally comprises generalizations drawn from empirical and verified investigation, the sociologist strives to understand and to achieve prediction of human conduct and social phenomena. Values are among the data which he studies and not the end product of his labours.

This article on sociology is divided into the following sections and subsections:

I. HISTORY OF SOCIOLOGY

The word sociology was first used by Auguste Comte (1798–1857) in 1837 in a series of lectures on which his famous work *Positive Philosophy* (6 volumes, 1830–42) was based. His coining of "sociology," a hybrid of Latin and Greek still disliked by many, has led him to be regarded by a number of writers as the founder of sociology. Yet, his conception of sociology as an all inclusive general social science—a synthesis of all knowledge about "humanity" which he used in the sense of the universal society—and his promotion of "positivism" as the foundation for the mystical religion of humanity which he proclaimed in his later life are widely divergent from contemporary conceptions and practices of sociology. Comte did make a great contribution to the social sciences in general in producing a synthesis of the social thought of the century which preceded him, beginning with the work of David Hume, in laying great stress on the application of the positive method to social phenomena—a method of observation, experimentation, and comparison—and in his evaluation of the importance of studying laws of succession and association of phenomena rather than cause. It is more accurate to say that Comte in his classification of the sciences and his description of their development made a place for and heralded the approach of sociology, rather than that he founded it.

The history of sociology, in a loose sense, began centuries before Comte, but, like all history, has no clear-cut beginning. Historians of sociology, at least those who have published histories of sociology or of social thought, have variously begun their accounts with ancient civilizations (*e.g.*, Pitirim Sorokin, Joyce O. Hertzler, or Emory S. Bogardus), with the Greeks (*e.g.*, Floyd N. House, Harry E. Barnes, or James P. Lichtenberger), or with 19th-century thought (*e.g.*, P. Barth, Albion W. Small).

If the genesis of sociology is traced to folk, philosophical, political, and legal thought about man and society, then sociology had its beginnings in the earliest records of human thought in the ancient civilizations of Egypt, Babylonia, Assyria, Persia, India, and China. If sociology is rigidly defined as a specialized empirical social science, then it may be said that it certainly did not begin before the 20th century. It is much less important, however, to fix a precise date for the beginning of sociology in the narrower sense than it is to have an understanding of what it aims to do, of the problems with which it is concerned, and of some of the main currents of thought which led to its emergence.

1. Social Thought Prior to the 19th Century.—The history of sociology in the broader sense is essentially the history of social thought through the ages—a heritage which sociology shares with all the sciences, natural and social. Although various aspects of social thought, from the earliest human records which can be traced back 5,000 to 6,000 years to the dawn of the 19th century have special implications for the development of sociology, only the briefest mention can be made of them. Ancient literature and relics contain keen insights into interpersonal relations, group life, social control, social organization, social stratification, human nature, and social institutions, including the family, the state, and property. Early social thought was largely of a common-sense nature, sporadic, traditional, and unverified, and suffused with the interventionism of the supernatural.

Systematic social thought, at least in a form which has been reasonably well preserved, originated with the Greek philosophers. Beginning with about 600 B.C. a remarkable series of Greek thinkers became preoccupied first with the world of nature and then with the world of man. The Greek philosophers, and especially Plato and Aristotle, provided penetrating analyses of the relation of man to society, of social institutions, and of social processes; contributed to important methodological developments; and originated basic elements of social theory which have remained in the focus of intellectual discussion ever since.

Despite the setting of the stage for the development of science by the Greeks, natural science did not develop until 2,000 years after Thales (*c.* 624–*c.* 546 B.C.) and social science until more than 2,000 years after Aristotle (384–322 B.C.).

By the 15th and 16th centuries, however, the combined influences of a number of events produced the revival of learning manifested

in humanism and naturalism, and the way was clear for the resumption of critical social thought. By the end of the 17th century, natural science had forged a relatively secure place for itself, and thought about the social as well as the natural world had become largely secularized.

2. 19th-Century Influences.—By 1800 many interrelated intellectual pathways led to the consideration of various aspects of man and society and a number of them contributed to the emergence of the science of sociology. The way had been paved for the application of scientific method to social phenomena (compare SCIENTIFIC METHOD for distinctions among the disciplines considered sciences) by such men as G. Vico (1668–1744) and C. Montesquieu (1689–1755); quantitative methods had been applied to population phenomena by the "political arithmeticians" such as William Petty (1623–87) and John Graunt (1620–74); and important insights into central sociological problems had appeared in the writings of the "Scottish moralists," Francis Hutcheson (1694–1747) and Adam Ferguson (1723–1816).

Major influences on the development of sociology in the 19th century were exerted by scholars who dealt with substantive and methodological problems which, at least implicitly, helped delineate a field and methods for the social sciences in general, as well as for sociology in particular. These writers may be classified into groups, not mutually exclusive, organized around leading ideas. The ideas may be broadly grouped into three categories: first, those focusing on problems which set the stage for, or themselves became, central problems in sociology; second, those emanating from biology, which exerted an important influence on early sociology; and third, those concerned with methodology and techniques of research. In addition to these ideas, the emergence of sociology was also influenced by ideas and programs of social reform, which on the one hand stimulated interest in sociology and on the other confused its role as a science.

Ideas Related to Central Problems.—The writers contributing to this category of ideas included the scholars who dealt with the nature of the historical process, the distinction between the state and society, the nature of culture, folk psychology, the analysis of self-consciousness, the influence of the physical environment, the role of "social forces" and "interests," the economic activity of man, and population problems.

The writers who inquired into the nature of the historical process sought to relate successive events and to generalize from the experience of history. They devoted considerable attention to the question of whether history could or should generalize as against reporting unique events. Important participants in this development included Kant, Fichte, Hegel, Marx, Wilhelm Dilthey, and Wilhelm Windelband.

In early social thought the "social" was largely synonymous with the "political." Preoccupation with the state precluded attention to other aspects of society. The scholars who differentiated between the state and society helped to point up the need for the study of the nonpolitical aspects of the social order. Thus they made explicit in their affirmation or opposition the need and place for a new science. They included such men as Robert von Mohl (1799–1875), H. von Treitschke (1834–96), and Ludwig Stein (1859–1930).

Also made explicit during the 19th century was the idea of culture as a thing in itself. It was emphasized that culture, both in its material and nonmaterial aspects, could be studied historically and comparatively to illuminate the nature of man and society. Early culture historians and anthropologists included Friedrich Ratzel (1844–1904), Adolf Bastian (1826–1905), Alexander von Humboldt (1769–1859), and Lewis H. Morgan (1818–81). These men, and others, collected a mass of data on the cultures of diverse people, and their efforts to compare, analyze, and explain similarities and differences helped to stimulate the sciences of anthropology and sociology.

Another group of writers were expressly concerned with "folk psychology" and with the relation of folk psychology to the individual mind. Their analysis of folk psychology and the "collective mind" led them to explanations of human nature and of individual traits as arising from culture. These writers defined one of the central problems of sociology in its contemporary sense in highlighting the dependence of a person on the social group and describing personality as a subjective aspect of culture. They included such men as Johann F. Herbart (1776–1841), the Grimm brothers Jacob (1785–1863) and Wilhelm (1786–1859), Moritz Lazarus (1824–1903), H. Steinthal (1823–99), and Wilhelm Wundt (1832–1920).

Closely related to the study of folk psychology and the nature of the mind was the analysis of the growth of self-consciousness. The description of self-consciousness as a phenomenon dependent upon society and arising in social interaction continued to play a central role in 20th-century social psychology. Contributors to this analysis included Von Humboldt, Georg Simmel (1858–1918), and James M. Baldwin (1861–1934).

Although ancient and early modern scholars were concerned with the influence of environment, various streams of thought during the 19th century led to more intensive investigation into the influence of geographic factors on social organization and human behaviour. Geographers and anthropogeographers who investigated this problem varied in their conclusions from strict environmental determinism to more modern indications of the limiting influences of physical environment. These writers helped pave the way for the science of sociology in general, and more specifically for contemporary sociological interest in human ecology and regional studies. They included such men as Carl Ritter (1779–1859), H. T. Buckle (1821–62), P. G. F. Le Play (1806–82), and Vidal de la Blanche (1845–1918).

Another central problem in early sociology originated in the writings of the scholars concerned with "social forces," "interests," and the social process. The notion of social forces appeared in the historical literature in efforts to explain events in terms of their underlying and antecedent factors. The notion, however, was also used more generally to explain basic human and group behaviour. Among the writers who sought explanations of behaviour in social forces and interests were Buckle, Ludwig Gumplowicz (1838–1909), Gustav Ratzenhofer (1842–1904), and Gabriel Tarde (1843–1904).

The development of economics during the 19th century represented the emergence of perhaps the first of the social sciences to a position of respectability and general acceptance. The description of the economic man as a rational, calculating, hedonistic person stimulated interest in individual motivation and in the analysis of rational behaviour. The emphasis placed by economic writers on the division of labour led to investigation into its relation to the social structure and process. Especially noteworthy among the writers on economic matters were Adam Smith, David Ricardo, Jeremy Bentham, and J. S. Mill. An important offshoot of classical economic thinking was that represented by critics of the new industrial order and of classical economics, manifest largely in the writings on socialism. In this literature the names of Karl Marx and Friedrich Engels were outstanding.

Closely tied in with, and contributing to, economic thinking were the discussions of "the population problem." Dramatized by Malthus, whose "law of population growth" was originally presented as a refutation of Condorcet's and William Godwin's notions of perfectionism, consideration of the relation between population and means of subsistence occupied considerable attention in the world of practical affairs, as well as among scholars. Writers concerned with population and with the antecedents and consequences of population growth included, besides Malthus, Francis Place (1771–1854), Archibald Alison (1792–1867), Adolphe Quételet (1796–1874), Marx, and Herbert Spencer.

Ideas from Biology.—Important developments in biology during the 19th century, climaxed by the theory of evolution, contributed both directly and indirectly to early thought in sociology. The influence of biology on sociological thinking may be considered under four groups of ideas; namely, the theory of evolution, the "organic analogy," the problem of "heredity versus environment," and the theories of racism.

One of the most dominant influences on 19th-century thinking, in general, was that exerted by the theory of evolution. Stimulated by Malthus' discussion of the "struggle for existence" and

with the taxonomic labours of Linnaeus available, Alfred R. Wallace and Charles R. Darwin independently published their contributions which made evolution the cornerstone of social as well as of biological thinking for decades. Evolutionism was quickly adopted by students of social phenomena as a basic explanatory principle applied to the social order, as well as to the biological. Among the writers who adopted social evolutionism were Walter Bagehot (1826–77), John Fiske (1842–1901), Gumplowicz, Ratzenhofer, and Spencer.

In addition to providing the principle of evolution, biology also exerted an important influence on the development of sociology in the writings of the scholars who compared society with an organism. Impressed by the organic character of society, a number of writers described the social order in terms paralleling the biologist's description of an organism. The organic analogy, while subject to the limitations of all analogies, did perform the function of directing attention to the organic character of society and stimulated more intensive inquiry into the nature of the structure and function of the social order. It led to consideration of those aspects of society that made the social whole more than a sum of all its parts. Among the writers to utilize the organic analogy were Comte, Spencer, Albert Schäffle (1831–1903), Paul von Lilienfeld (1829–1903), René Worms (1869–1926), and J. Novicow (1849–1912).

Influenced by the prominent place of variability in the theory of evolution, and on the basis of studies of individual differences, the attention of a number of scholars was devoted to the consideration of the relative roles of heredity and environment in human behaviour. Individual differences were recognized as attributable to both hereditary and environmental factors. Writers with a biological orientation tended to stress the greater importance of heredity: first, as the basic factor in explaining individual differences in abilities and behaviour; and second, as the basic factor underlying social change. Especially prominent in the development of these ideas were Sir Francis Galton (1822–1911) and Karl Pearson (1857–1936).

A special variation of the efforts to explain human behaviour in biological terms was found in the ideas of a number of writers on racial superiority and inferiority. On the whole, this literature, while often ornamented with the trappings of biological findings, was propagandistic in character and tended to play up the alleged superiority of the so-called Aryan or Nordic race. They are mentioned here because they stimulated a widespread controversial literature which helped to focus attention on historical and cultural, as well as biological, factors in accounting for racial as well as individual differences. Among the writers who contributed to the literature of racism were Arthur de Gobineau (1816–82), G. V. de Lapouge (1854–1936), and Otto Ammon (1842–1916). (*See* also INTERRACIAL RELATIONS: *Racialist Thinking*.)

Ideas Relating to Methodology and Techniques.—The writers briefly treated above contributed to some of the central substantive problems of emergent sociology. Equally important were the writers who helped develop a methodology for sociology. These writers may be considered in three groups; first, those who contributed to general methodology; second, those who contributed to statistical techniques; and third, those who contributed to the "social survey."

Noteworthy, first of all, were the methodological contributions of a number of historians who, in grappling with the problems of method in history, made important contributions to social science in general. F. K. von Savigny (1779–1861) stressed the methodological implications of continuity in the historical process; K. F. Eichhorn (1781–1854) called attention to the complexity of social phenomena and the importance of the idea of multiple causation; B. G. Niebuhr (1776–1831) emphasized the necessity of being critical of sources and of the role of the investigator; and Leopold von Ranke (1795–1886) gave great impetus to the habit of documentation and annotation. Also of great importance were the methodological contributions of Comte, Dilthey, and Windelband, who grappled with the general problems of social science methodology as contrasted with method in the natural sciences.

Simultaneously with the consideration of general problems of method there were important developments in the application of mathematics to the analysis of social data. Building particularly on previous work in probability theory, as well as in general mathematics, statistical techniques were evolved during the 19th century suitable for the treatment of social phenomena. Important contributors to these developments included P. S. Laplace (1749–1827), Quételet, Carl Friedrich Gauss (1777–1855), Adrien Marie Legendre (1752–1833), Francis Galton, and Karl Pearson.

Significant from the standpoint of method as well as for the substantive data it provided was the "social survey" as it developed during the 19th century. The social survey was essentially a fact-finding enterprise designed to illuminate social and economic evils in a specific area for purposes of ameliorative action. Although action oriented, the social survey provided basic data for research and stimulated widespread interest in the study of social, economic, and political problems. Some of the more important social surveys were those conducted by Le Play, Sir Edwin Chadwick (1800–90), and Charles Booth (1840–1916). The latter's famous report, *Life and Labour of the People in London* (17 volumes, 1889–1903), set a pattern for similar surveys in other countries.

Other 19th-Century Influences.—In addition to the developments outlined above, sociology was greatly influenced by the increasing attention during the 19th century to the social, economic, and political problems arising from the accelerated pace of the Industrial Revolution and urbanization. These problems were dramatized by extreme manifestations of poverty, high mortality rates, urban slums, abuses of labour, political unrest, and political corruption. Nineteenth-century critics of the industrial order, philanthropic and utopian efforts to deal with the more severe social and economic conditions, the literature on socialism and anarchism, and increasing awareness of and efforts to deal with the problems of a rapidly changing social order constituted an important part of the 19th-century climate in which sociology emerged as a distinctive field.

Pioneer Sociologists.—Nineteenth-century writers included a number of men who are generally regarded as the founding fathers of sociology. Early sociologists were not the product of any one nation. In France they included, in addition to Comte, Émile Durkheim (1858–1917), Lucien Lévy-Bruhl (1857–1939), Gabriel Tarde, and Gustave LeBon (1841–1931); in Germany, Ferdinand Tönnies (1855–1936), Georg Simmel, and Max Weber (1864–1920); in Austria, Ludwig Gumplowicz and Gustav Ratzenhofer; in Russia, J. Novicow and Maxim Kovalevsky (1851–1916); in Italy, Scipio Sighele (1868–1913) and Vilfredo Pareto (1848–1923); in England, Herbert Spencer (1820–1903), Leonard T. Hobhouse (1864–1929), and Patrick Geddes (1854–1932); and in the United States, Lester F. Ward (1841–1913), William Graham Sumner (1840–1910), Albion W. Small (1854–1926), Franklin H. Giddings (1855–1931), Edward A. Ross (1866–1951), and Charles Horton Cooley (1864–1929). Other countries also developed pioneer sociologists, but their works were, for the most part, untranslated and they did not enter into the mainstream of sociological development.

Of the pioneer sociologists, perhaps the most influential in the impact of their work on other sociologists were Durkheim, Weber, and Cooley. Durkheim provided a clear delimitation of the field of sociology as a science devoted to the study of "the social fact." Social facts, which included forms of behaviour, thought and feeling, could be studied, he emphasized, as things in themselves. The social fact was exterior to the individual, anterior to him, and exercised a constraint upon his behaviour. It was to be studied as a collective representation and not in its individual manifestations. In his *The Rules of Sociological Method* (George E. G. Catlin, ed.), he described what he regarded as the field and the method for sociology. In other publications, notably *Suicide, a Study in Sociology* (1897, translated by John A. Spaulding and George Simpson), the *Division of Labour in Society* (1893, translated by George Simpson), and the *Elementary Forms of the Religious Life* (1912, translated by J. W. Swain), Durkheim provided examples not only of the application of his methods but also of notable pioneer empirical investigations.

Weber also delimited a field for sociology. To Weber, sociology was a science devoted to the interpretation and understanding of social behaviour so as to achieve its prediction. He defined "social behaviour" as behaviour carried out according to the intention of the acting individual in reference to the behaviour of others. Sociological analysis was to be devoted mainly to getting at the intentionality of social behaviour. This was to be achieved through gaining an "understanding" of social behaviour: intellectually, if the behaviour was rational, by recognizing the logic of the means-end relationship; by means of empathy, if the act was irrational, by projecting oneself into a situation and experiencing the emotional context involved. Weber made an important methodological contribution in his description and use of "ideal type" concepts as tools of analysis against which to observe and analyze real situations. He also recognized the utility of statistical methods, especially the fundamental notions of probability and association as tools of research. Weber's consideration of bureaucracy and social stratification contributed materially to sociological investigation of these subjects. Some of his more important publications available in English are *The Theory of Social and Economic Organization* (translated by A. M. Henderson and Talcott Parsons), *From Max Weber: Essays in Sociology* (translated by H. H. Gerth and C. Wright Mills), and *The Methodology of the Social Sciences* (translated by Edward A. Shils and Henry A. Finch).

Cooley, in his doctoral dissertation *The Theory of Transportation* (1894), contributed in an important way to interest in human ecology as a field of sociology. In this work he dealt with transportation and the general economic base as a substratum of social organization. His subsequent work resulted in major contributions to general sociology and social psychology. He began with a theory of human nature and the genesis of the self, as set forth in his *Human Nature and the Social Order* (1902). His study of personality led him to the study of social structures and forms as treated in his *Social Organization* (1909). He completed what may be regarded as a system of sociology in his analysis of collective life in *Social Process* (1918). Cooley's treatment of the "primary group," the "looking-glass self," communication, and the problem of society and the individual provided subsequent sociologists with an important part of their conceptual framework. His methodological contributions lay largely in his suggestive work in ecology on the one hand, and in his description of "sympathetic introspection" as a tool of research on the other.

Mention should also be made of Small as one of the important early sociologists, particularly for his contribution to the development of sociology as an academic discipline and as a profession. On the substantive side, Small, although he changed his position in the course of his career, helped define the scope of sociology as a science; played an important part in introducing European, and especially German, sociological thinking into the United States; and laid great stress on the development of method as a prerequisite to the advance of sociology as an empirical science.

It is not possible, of course, even to summarize the work of all of the individual builders of sociology. Most of the founders had in common a penchant for system building and, no doubt under the influence of the brilliant and dramatic 19th-century scientific successes in other fields such as that represented by Darwin's theory of evolution, attempted to account for man and the social order by broad, comprehensive, and global principles. Most of the systems were characterized by universal explanatory schemes, such as "evolutionism," or by monistic explanations of human behaviour such as "imitation."

A number of sociologists subscribed to the view that sociology was essentially a normative, meliorative discipline. They engaged in great debates over nominalism and realism, as manifested in the discussions of the "atomistic" or "organic" conceptions of society, or the distinction between the individual and social aspects of the group; over the relation of sociology to values; over the priority of the study of the form as opposed to the content of individual and group behaviour; over the role of the "biological," the "psychological," and the "sociologistic" factors or levels of explanation; over the materialistic and idealistic conceptions of the historical process; over the suitability of natural science methods for the study of social phenomena and especially the applicability of quantification, or statistical techniques; over the conception of sociology as the general social science or one of the special social sciences. In the works of the pioneers these and other issues, as they bore on the emergence of a science of society, were clarified; and if the problems were not resolved, their discussion was, on the whole, exhausted, so that points of departure were provided for subsequent students.

The common and essential characteristic of these early sociologists was that they were, in the main, still social philosophers rather than social scientists. Their basic methodology was still grounded in speculative thinking rather than empirical investigation, although to be sure there were some notable exceptions (*e.g.*, Durkheim's *Suicide*, 1897, and Sumner's *Folkways*, 1906). They were concerned more with discussions of what sociology should be and should do rather than with the doing of it. They performed an important function in making explicit some of the basic issues, consideration of which was perhaps prerequisite to the emergence of sociology as an empirical science; in delimiting an area of investigation; in posing many of the specific problems of sociology; in framing a methodology and providing a number of research techniques; in contributing materially to the development of sociological concepts; and in providing important insights which influenced the course of subsequent developments in sociology.

3. 20th-Century Developments.—System building in sociology continued into the 20th century, and for the first two decades there was also a sustained interest in the broad general problems of the type indicated above. The distinctive marks of 20th-century sociology, however, lie in its delimitation as a separate social science; in the emphasis placed upon research as the primary task of sociology; in the emergent conception of theory as a prelude to, and product of, research rather than an exercise in armchair speculation; in the broadened participation of sociologists in empirical investigation; and in the increasing use of statistical and experimental or simulated experimental methods. Accompanying these developments was a great increase in the number of sociologists and in the widespread appearance of sociology in university and college curricula, especially in the United States, as a recognized academic discipline. In these developments, sociology, if it did not become a science in a rigorous sense, at least definitely moved in that direction. The great bulk of sociological publications comprised reports of empirical research, and broad social speculation ceased to be a major preoccupation of sociologists, especially in the United States.

The shift from speculative social thinking to empirical research was led and fostered by the generation of sociologists who followed the pioneers and who, for the most part, were their students and sometimes their disciples. The trend toward empirical investigation was most manifest in the United States, partly because of the availability of greater resources for research. Research grants by the large foundations (such as the Rockefeller Foundation and the Carnegie Corporation of New York), expanding research appropriations by the federal government, especially for agricultural research at the outset, and increased expenditures by action agencies for "applied research" provided the means for the conduct of empirical investigations. Research activities were stimulated, also, through the development of professional organizations whose primary objective was the encouragement of such activity. The most important of these were the American Sociological Association, founded in 1905 as the American Sociological Society, and the Social Science Research Council, which was organized in 1923. Sociological research activity, however, was by no means confined to the United States.

In the United States the transition from social speculation to empiricism was spearheaded by such men as W. I. Thomas, Florian Znaniecki, Robert E. Park, E. W. Burgess, W. F. Ogburn, Ellsworth Faris, Richmond Mayo-Smith, R. M. MacIver, L. L. Bernard, F. S. Chapin, and H. W. Odum. Not all of these men themselves pioneered in research activity, but they all showed an enthusiasm for, and interest in, research which they passed on to their students. Early 20th-century examples of empirical investigation included such works as Sumner's *Folkways* (1906), Paul U.

Kellogg's *The Pittsburgh Survey* (1909–14), C. J. Galpin's *The Social Anatomy of an Agricultural Community* (1915), and W. I. Thomas and Florian Znaniecki's *The Polish Peasant in Europe and America* (1918–21). In addition, works which, while themselves not empirical investigations, contributed inestimably to the increasing tempo of research activity included Park's essay "The City: Suggestions for the Investigation of Human Behavior in the Urban Environment" (1915) and Park and Burgess' *Introduction to the Science of Sociology* (1921). The former provided a framework for urban and ecological research. The latter brought together in a systematic fashion the insights and concepts of earlier writers set in a framework oriented to research. Pursuant to these publications, a series of monographs were published by young sociologists, trained at the University of Chicago, which constituted the first mass series of empirical investigation in sociology.

After about 1940, the relatively large volume of discrete research reports in sociology led some sociologists to feel that the pendulum had swung too far away from theory. Pure fact finding was criticized as being as unproductive as pure speculation. In consequence, there was a discernible attempt on the part of sociologists to tie their investigations to relevant theory and to direct their research activities toward the testing of explicitly stated, verifiable hypotheses.

Sociology was slower to develop in Europe than in the U.S. during the 20th century, especially in research. Up to World War II, in England a mere handful of men had claim to the designation of "sociologist," although a number of prominent scholars had contributed to the development of various aspects of sociology. The situation was similar on the continent, with the exception of France and Germany. Although an important literature was developed which contributed materially to sociological insight and theory, empirical research did not reach the stage or magnitude of development in either France or Germany that it achieved in the United States. In France, sociological activity was closely interwoven with that of anthropology and, in large part, not clearly differentiated.

After World War II, however, there was evidence of increasing interest in sociology in Europe and in other parts of the world. The number of chairs in sociology at recognized universities grew considerably. An International Sociological Association was established under the sponsorship of the United Nations Educational, Scientific and Cultural Organization in 1949, and Louis Wirth (1897–1952), of the University of Chicago, was elected its first president. (P. M. Ha.)

II. FIELDS OF SOCIOLOGY

There is no generally accepted classification of the fields within sociology. The classification used below, for purposes of convenience in summarization, is arbitrary. The fields listed are closely interrelated and not mutually exclusive. They serve to denote general areas of specialized interest for research and teaching purposes.

A. Social Organization

Social organization, the core field of sociology, is concerned with the description and scientific analysis of human organization. The study of social organization includes the full range of human groups, from the smallest—the family and the play group—to the largest and most complex, the nation-state. It also includes industrial, political, educational, and religious institutions. The term covers social stratification, social mobility, and the organization of occupations, professions, and ethnic and racial groups. It involves study of the sources of social change and analysis of social control; that is, the informal and formal rules by which men govern and regulate their social relations.

Since ancient times, men have recognized that social groups are more than the mere sum of individuals. Human groups have a character apart from the characteristics of their members. Often this has been called the moral order or the social order. Philosophers have traditionally sought to understand man's ability to produce a stable social order and the reasons for breakdowns of the social order. The modern sociologist who studies social organization is continuing this tradition of inquiry. Instead of speculation, he seeks to make use of the methods and empirical techniques of social research.

The sociological study of organization is closely related to similar research interests in other social sciences. Social anthropology (*q.v.*) generally confines its investigation to the social organization of primitive societies, but the literature of the two fields have many areas of common interest. The work of social anthropologists, particularly those of France and to a lesser extent those of England, has had a direct influence on the study of social organization in the United States. Since World War II, social anthropologists have shown increased interest in modern societies. The convergence of the two fields has been accelerated as primitive societies throughout the world have become modernized. Social organization research is linked to economics in the study of industrial organization and of economic development, especially in underdeveloped nations. Likewise, politics has been analyzed as a form of social organization under the name of political sociology and political behaviour.

The widely ranging subject matter of social organization is given unity by the major theoretical approaches to the field which find their origin in the writings of European scholars. One major stream of thought is that of the "economic determinists" who see social relations reflecting the mode of production and economic interests. While "economic materialism" is most closely associated with the name of Karl Marx, this point of view has found expression in a variety of sociologists unconnected with Marx's political philosophy. In the United States economic determinism was transformed into a broad theory of technological development by William F. Ogburn, a leading figure in the "Chicago empirical school" of the University of Chicago. In his influential book *Social Change* (1922) he developed the theory of "cultural lag," in which he saw technology changing more rapidly than other aspects of social organization—such as culture, social knowledge, and law. Therefore, he suggested, technological development unless guided would produce instability and disruption in the social order. The economic and technological factors in social organization are also prominent in the human ecology school which was developed at the University of Chicago by Robert E. Park and his associates. A later important reformulation of the technological emphasis was presented by William F. Cottrell in *Energy and Society* (1955) in which he related the forms and uses of energy to the processes of social change.

The other stream of thought is more diffuse but has its central focus in the importance it attaches to social values, social norms (social rules), and communication systems of human groups. These writers emphasized the social bonds that men develop in the pursuit of their group interests. Émile Durkheim, in his *Division of Labor in Society* (1893), expounded the basis of the "social rules" school of social organization. It is not the technology per se but the forms of social solidarity that regulate human behaviour. In the primitive society, he saw "mechanical solidarity"—a repressive form of social organization—based on a simple division of labour. In modern society, with its complex social forms, social solidarity becomes "organic"—less repressive but more unstable and weaker. Ferdinand Tönnies formulated a related theory in which he saw social organization being transformed from *Gemeinschaft* (community) to *Gesellschaft* (society). In a *Gemeinschaft*, men are organized by social rules that are traditional and effective, whereas in a *Gesellschaft* rational self-interest operates to weaken traditional bonds. Louis Wirth in his essay "Urbanism as a Way of Life" (1938) applied these concepts to the modern metropolis. Robert Redfield (*q.v.*), the social anthropologist, expressed this outlook as the folk-urban continuum: folk society represented the social order based on a simple, small, isolated, and stable organization; the urban society is the complex, large-scale, and heterogeneous human settlement (1941).

Max Weber rejected economic determinism and emphasized social values, ideology, and beliefs systems in social organization. His *The Protestant Ethic and the Spirit of Capitalism* (1930) presented the thesis that religious beliefs were important ingredients in the development of Western industrialism. Weber analyzed the status, or noneconomic, aspects of occupation—that is,

the prestige and esteem given to different types of occupations and professions. Social status for Weber was an elemental aspect of human behaviour and, together with organizational authority, accounted for much of the form of modern social organization.

Two major efforts have been made to unify these diverse theories of social organization. Talcott Parsons' *The Structure of Social Action* (1937) represents a comprehensive effort to blend the common elements in the work of Durkheim, Weber, and others who make use of social values and social norms. While Parsons' terminology has not necessarily been generally accepted, his writings gave direction to the influential "structural functional" or "functionalism" school. Parsons is concerned with a very general theory of social organization which is not bound by concrete historical periods and which is applicable to both simple and complex social groups. His key concept is the social system, the pattern of role relations and institutions that develop among men.

Harold Lasswell and Abraham Kaplan in *Power and Society* (1950) developed an alternative synthesis of social organization theory which seeks to bridge both economic determinism and social values. For these authors, social class was too broad a concept to describe modern social organization. Instead they analyzed society in terms of more specific skill groups. In their framework, power relations are central concepts.

Despite the vigorous efforts to construct theories of social organization, the major accomplishments of the field rest mainly on the more empirical research into concrete patterns of social stratification and into particular types of organization such as community organization, bureaucracy, and the like.

1. Social Stratification.—By social stratification, the sociologist means the layers of a society which come about because social groups differ in occupation, income, prestige, and style of life. All groups are characterized by their stratification. Social stratification systems are based on hierarchies of rewards and privileges as well as differences in skill, education, and power. Under the impact of industrialism, social stratification undergoes vast changes. Therefore sociologists have accumulated a considerable body of empirical research literature on patterns of social stratification and social mobility. The earliest studies of social stratification include the purely descriptive works of Europeans such as P. G. F. Le Play and Charles Booth who sought to record the income and living conditions of family groups, especially the lower classes, whose style of life was being disrupted by the advent of the factory system. In the United States the social survey movement (mentioned above), sponsored by the pre-World War I social reformers, collected descriptive materials for purposes of social planning.

But it was in the works of the founders of American sociology in the early 20th century—for example, William Graham Sumner, Charles H. Cooley, and William I. Thomas—that there emerged a general concern with understanding the origins and consequences of social stratification. William G. Sumner, who worked extensively in primitive societies (*Folkways*, 1906), was one of the first to analyze social class relations in the United States (*What Social Classes Owe to Each Other*, 1883). Charles H. Cooley in his writings on the disruption of the moral order of modern society became concerned with the impact of class conflict on social values (*Social Organization*, 1909). In order to account for the social and personal disorganization which the Polish emigrant was experiencing in the United States during the first part of the century, W. I. Thomas and Florian Znaniecki presented their classic study, *The Polish Peasant in Europe and America* (1918–21), which has become a prototype of social stratification research.

Popular ideology in the United States has tended to ignore the existence of social classes, but the depression of the 1930s brought an increased interest in social stratification and social inequality. Under the impact of economic determinist thinking, numerous studies were done seeking to describe the consequences of social change on the class structure. C. Wright Mills (1916–1962) was one of the most energetic of this group, and his book *White Collar* (1951), which describes the decline of the old independent small business class and the rise of the salaried employee, represents this approach.

Other empirical sociologists undertook to demonstrate that social stratification was not the exclusive result of economic factors. Social scientists such as F. S. Chapin developed scales for measuring the socioeconomic position of families. By applying the techniques of social anthropology, W. Lloyd Warner and his associates prepared a series of research monographs on the social stratification systems of small communities which focused on friendship, social contact and marriage patterns, and voluntary associational life. Warner's findings underline that a person's position in the social structure is not based on economic factors per se but involves popular conceptions of occupations and social prestige.

With the growth of sample surveys and public opinion polling, it became possible to extend the study of prestige and social stratification beyond the confines of particular small local communities. Paul K. Hatt, by means of the National Opinion Research Center, collected the first nationwide data on the public's attitudes toward a wide range of occupations and established the general pattern of occupational prestige in the United States. Richard Centers, using a similar methodology, described the popular images toward the social class system (*The Psychology of Social Classes*, 1949).

Research into the status aspects of social stratification has probed the importance of race, ethnicity, religion, and age as a basis for social distinctions. Edward Franklin Frazier's classic study of *The Negro Family in the United States* (1939) focused not only on the internal dynamics of the minority family but also on the position of the Negro family in the larger stratification system based on Negro-white relations. Gunnar Myrdal in *An American Dilemma* (1944; rev. ed., 1962) presented a monumental report on the social position of the Negro, while Everett Hughes, in *French Canada in Transition* (1943), presented a comprehensive study of the changing balance of social stratification in Canada between the English Protestants and French Catholic stock. The extensive literature on social stratification in the United States and elsewhere was effectively summarized by Bernard Barber in *Social Stratification: a Comparative Analysis of Structure and Process* (1957) and also by Joseph A. Kahl in *The American Class Structure* (1957).

2. Social Mobility.—A central topic in empirical studies of social stratification has been the measurement of the amount of social mobility; that is, the movement of an individual or a family from one social position to another, either upward or downward. The theoretical foundation for the study of social mobility was presented by Pitirim Sorokin (*Social Mobility*, 1927) and Joseph Schumpeter (1915). With the accumulation of material wealth in an industrial society, sociologists have addressed themselves to the question of whether the opportunities for upward social mobility have decreased. Studies of the available data for the United States since 1900 permit the conclusion that there has not been a decline in opportunities for upward social mobility. This is based on historical analysis of specific communities in, for example, Natalie Rogoff's work on Indianapolis (1953) and on the examination of particular leader groups such as businessmen (F. W. Taussig and C. S. Joslyn, 1932, and W. Lloyd Warner and James C. Abegglen, 1955). While the opportunity for mobility has not decreased, avenues have changed and higher education has become more of a prerequisite for upward mobility.

Sociologists are in agreement as to the major changes in the social pyramid during the 20th century. There has been a growth in the size and composition of the middle-income and middle-status groups, while the lower groups have remained stable or declined. The boundaries between social groups have become blurred, rather than sharper and more distinct, and within social groups there is greater social diversity. In an industrial society, upward mobility is accompanied by downward mobility for an important minority. Changing technology and old age force some groups to decline in economic and social status.

Social stratification and social mobility studies, as they relate to the organization of a whole nation-state, supply an important basis for comparative social organization research. In connection with the Subcommittee on Social Stratification of the International Sociological Association, studies in various industrialized countries

on social mobility were completed: Great Britain (D. Glass, 1954), Germany (M. Janowitz, 1958), France (Bresard, 1950), Sweden (G. Carlsson, 1958), Denmark (K. Svalastoga, 1960), Netherlands (van Tulder, 1956), and Japan (K. Odaka, 1959).

The Russian Research Centre of Harvard University studied social mobility in the Soviet Union on the basis of interviews with refugees (Alex Inkeles and Raymond Bauer, 1959). While these studies do not permit precise comparison, it appears that the United States probably has a higher rate of social mobility than other industrialized countries, although the differences are not as great as generally assumed and patterns are tending to converge among these different countries (S. M. Lipset and Reinhard Bendix, 1959). As sociologists deepen their knowledge of social mobility they become more concerned with the consequences of social mobility. Upward mobility brings social benefits in increased income, broader social perspectives, and greater participation in community and voluntary associations; it also has its disruptive consequences. Social mobility often tends to disrupt interpersonal relations and to increase marital tensions and mental illness.

3. Community.—Closely related to the study of social stratification has been the interest in community research, which has developed a continuous tradition of firsthand observation. The original empirical community study was the description of a midwestern town reported in Albion Small and George Vincent's *Introduction to the Study of Society* (1894). Since then, there has been a continuous flow of studies of small communities, local communities in metropolitan areas, and ethnic and religious enclaves. The U.S. Department of Agriculture sponsored a series of rural community studies as part of its planning activities. The community study has been taken up wherever sociological research is practised throughout the world.

Of U.S. studies of smaller communities, the most well known are *Middletown* (1929) and *Middletown in Transition* (1937) by Robert and Helen Lynd; *The Social Life of a Modern Community* by W. Lloyd Warner and P. S. Lunt (1941); and *Elmtown's Youth* by August B. Hollingshead (1949).

Paralleling the studies of smaller communities has been the work in urban sociology, guided by a powerful curiosity to understand the rich and complicated texture of metropolitan life. Many of these studies were under the direction or stimulation of the University of Chicago in the 1920s and particularly Robert E. Park. His essay entitled "The City: Suggestions for the Investigation of Human Behavior in the Urban Environment" (1915) remains a guidepost. These sociologists were in turn influenced by Georg Simmel and his famous essay on "The Mental Life of the Metropolis" (1902). There was a strong literary quality in these original studies of urban life: Harvey Zorbaugh described *The Gold Coast and the Slum* (1929), Louis Wirth, *The Ghetto* (1928), Horace Cayton and St. Clair Drake worked in the Negro community (*The Black Metropolis*, 1945), and William Whyte wrote about the Italian slum in *Street Corner Society* (1943). These efforts were directed toward describing how the struggle for economic existence in the metropolitan community influences human values. The community was seen as a social system rooted in geography and bounded by the daily transactions of men and women as they exchange goods and services.

In the sociological view, the scope of a person's community has grown and its boundaries have become imprecise as society becomes more industrialized and more impersonal. One of the consequences of advanced industrialism has been suburbanization, the movement of persons out of the central business district, and thereby an increased separation of place of work and place of residence. A major theme in community studies has been the weakening of social bonds of community life, a growth of social disorganization, as families become more mobile in their daily existence and as modern careers require frequent moves from community to community.

In the 1950s a new cycle of community studies questioned the trends toward impersonality and disruption, or at least indicated the limits on these processes. Sociologists came to see the community of residence as the locus of essential functions, such as family formation, child rearing, the development of patterns of consumption and friendship. The newer community studies emphasized factors that make for stability and integration in residential communities (Robert Angell, 1947; Morris Janowitz, 1950; and the reports of the Detroit Area Study of the University of Michigan). Likewise, there has been increased interest in the operation of voluntary associations and political institutions of the local community which help regulate social and economic change. The prototype is Floyd Hunter's study of Atlanta, *Community Power Structure* (1953), in which he analyzed the top leadership of a metropolitan area as it controlled social welfare. Interest in the mechanics of social planning and particularly in urban renewal have produced a variety of investigations into the power realities of community life. American metropolitan centres have a pluralistic base of community power, in part because of the withdrawal of the top economic leadership from day-to-day decision. As a result, there has been a growth in the importance of professional political and organization leadership in the modern community.

4. Bureaucratic Organization.—In popular language, bureaucracy denotes an inefficient agency—public or private. (Compare, however, many meanings in BUREAUCRACY.) Bureaucracies may be defined as those large and specialized organizations men create in order to accomplish a specific task—economic, political, or even cultural. Following the writings of Max Weber, the essential characteristics of a bureaucratic organization have been identified as involving four factors: specialization; a hierarchy of authority; a system of rule, including rules for recruiting new personnel; and impersonality. The sociological analysis of bureaucracy centres on the factors that create organizational cohesion and effectiveness and those that impede administrative leaders from achieving their stated objectives.

Important general social organization treatises on bureaucracy and large-scale organization have been prepared by Chester Barnard, *The Functions of the Executive* (1938), Herbert Simon *Administrative Behavior* (1947), and Kenneth Boulding, *The Organizational Revolution* (1953). These writers described the common problems of modern bureaucracy regardless of the type of organization. They probed behind the formal rules and official organizational charts into the informal life of the organization—the status systems, authority relations, communications networks and patterns of reward and discipline which determine organizational effectiveness.

Large-scale organizations can be classified on the basis of their goals and their type of function—industrial, political, military educational, religious, or "therapeutic" (mental hospitals, correctional institutions). Research into the structure and operations of industrial organization was pioneered by Elton Mayo and his collaborators. Mayo took the measurement of productivity as the point of departure, and he emerged with the importance of small-group solidarity in productivity. He extended his work to link the factory system to the larger society. These studies have been repeated and modified by numerous investigators and supply an important basis for industrial sociology. The basic outline of the Mayo school with its strong perspective toward understanding the industrial system from the standpoint of managerial problems was presented by F. J. Roethlisberger and William J. Dickson in *Management and the Worker* (1939) and by T. N. Whitehead in *Leadership in a Free Society* (1936). A broad overview of industrial organization in the United States was formulated by Wilbert Moore, *Industrial Relations and the Social Order* (1946). Russian industrial organization was described by J. S. Berliner in *Factory and Manager in the U.S.S.R.* (1957); Reinhard Bendix in *Work and Authority in Industry* (1956) undertook one of the few efforts at cross-national comparison of industrial organization contrasting the United States, Great Britain, the U.S.S.R., and East Germany.

Because of the interest of sociologists in social reform, significant research is available on correctional institutions, social welfare, and health organizations, particularly mental health. The main theme of these researches has been the organizational barriers which prevent such institutions from achieving their stated goals. Donald Clemmer in 1940 wrote on the social organization of the

prison, and Gresham Sykes subsequently analyzed the maximum security prison (*Society of Captives*, 1958). Comprehensive treatment of the mental hospital was presented by Alfred Stanton and Morris Schwartz (1954), and by Ivan Belknap in *Human Problems of a State Mental Hospital* (1956). The National Institute of Mental Health of the U.S. Public Health Service sponsored social organization research on therapeutic institutions.

Interest in the organizational features of political parties was stimulated by the writing of Robert Michels on *Political Parties* (1915), who combined political polemics with sociological research. His so-called "iron law of oligarchy" argued that political democracy was impossible because the internal organization of political parties was inevitably undemocratic. For the United States, no adequate sociological studies exist on the structure of the major political parties or on the organs of government. The literature has been limited to specific case studies, such as Philip Selznick, *The TVA and the Grass Roots* (1949), and S. M. Lipset, M. Trow, and J. Coleman, *Union Democracy* (1956), which reports on the internal political structure of a small atypical union. More comprehensive sociological studies have been prepared on totalitarian political organization: Franz Neumann, *Behemoth* (1942) for Nazi Germany, and Barrington Moore, Jr., *Soviet Politics* (1950) and *Terror and Progress* (1954) on the Soviet Union.

Emerging areas of interest in bureaucratic organizations include educational institutions, Theodore Caplow and R. J. McGee, *The Academic Marketplace* (1958), Paul F. Lazarsfeld and Wagner Thielens, *The Academic Mind* (1958); the military, Morris Janowitz, *Sociology and the Military Establishment* (1959); the government bureau, Peter Blau, *The Dynamics of Bureaucracy* (1955); and the volunteer social service association, David Sills, *The Volunteers* (1958).

5. Small Groups.—Sociologists have been traditionally interested in specific small groups such as the family, the delinquent gang, or the neighbourhood play group. They collect extensive data on changing functions of the family and assemble statistics on marriage and divorce rates. Delinquent groups were first studied by Frederic Thrasher in the period after World War I (*The Gang*, 1936). Informal groups in voluntary associations and in leisure-time activities have also been the object of research. But the field of small groups as an essential aspect of social organization emerged only after 1945 when the importance of small primary groups was rediscovered. This was a rediscovery because Charles H. Cooley in *Social Organization* (1909) had earlier indicated on theoretical grounds the importance of these groupings for the social and moral order.

Primary groups are those small, relatively persistent, face-to-face associations—for example, family, peer groups, work groups. These groups relate the individual to the large units of social organization, the stratification system, the community, and large-scale organizations. Primary groups strengthen the human social bonds and condition their moral character, since in primary groups the demands of economic and political life are adjusted to the persistent needs of men. These aspects of primary groups were set forth by Edward A. Shils in his essay "The Study of Primary Groups" (1951). The primary group concept stands as a bridge between sociology and psychology because it is a mechanism by which individuals learn to accept and incorporate the social values in their social environment. This process has come to be called "socialization" and it extends throughout the entire life of the individual.

Primary groups supply the basis for social solidarity and group cohesion in large-scale organizations. Sociologists during World War II were impressed by the importance of primary groups in military life. Soldiers fought less for ideological and nationalist reasons and more for the respect and love of their immediate comrades. In industrial research, primary group structures are related to absenteeism, morale, and productivity, in that primary group solidarity has been found to be related to high industrial morale and low absenteeism. However, primary group solidarity results in opposition to managerial rules when workers feel themselves deprived or frustrated or when trade unions become a competing basis of loyalty and social solidarity.

Primary group relations have been found to be essential in facilitating a person's assimilation into a residential community. Children are the active agents in stimulating family friendships and neighbourly contacts. These primary group contacts and informal lines of communication operate to increase participation in community affairs. The political process and the influence of the mass media also work through primary group networks.

Lazarsfeld, Berelson, and Gaudet found in their empirical study of voting behaviour in Erie County (Ohio) that the pressure and influence of primary group members operated in the case of those persons who changed their voting intentions during the political campaign (*The People's Choice*, 1944; 2nd ed., 1948).

The study of primary groups has been developed by the use of specialized research methodologies. Sociometric techniques, devices by which persons express their preferences for friends and group members, make it possible to chart primary group structures. J. L. Moreno developed the sociometric techniques in *Who Shall Survive?* (1934), and they have been applied to a great variety of organizations from schools for delinquent girls to military combat teams. Primary groups are also studied by means of laboratory replications of real-life situations (K. Lewin, R. Lippitt, and S. K. Escalona, 1940). Sociologists also emphasize the importance of direct and careful observation of small groups in their natural social environment (George Homans, 1950).

6. Social Disorganization and Deviant Behaviour.—The basic concepts of social organization have been used extensively to explain deviant behaviour of individuals. Émile Durkheim's investigation of *Suicide* (1897) set the pattern for the field of social organization. He demonstrated that this form of extreme behaviour—generally considered to be a personal and psychological event—varied in different social groups and was related to the structure of society. He discovered that suicide rates varied among different nations, different religious groups, different classes and under different economic conditions. While subsequent researches have refined his methods and conclusions, his basic theory is still accepted as relevant for understanding deviant behaviour. The sociological basis of personal disorganization was enhanced by the writings of W. I. Thomas, who saw deviant behaviour as the result of a clash between primary group needs and cultural values of the larger society. These approaches have been applied to insanity, crime and delinquency, and alcoholism, as manifestations of social disorganization. In the area of psychopathology, Ellsworth Faris and H. Warren Dunham charted the higher incidence of severe mental disorders in working class areas (1939); those findings were amplified by August Hollingshead in *Social Class and Mental Illness* (1958). Hollingshead also concluded that the lower classes had fewer available facilities for dealing with mental illness. Research into the social factors of mental illness has called into question popular views, as it has in other areas of deviant behaviour, that with industrialism there is a marked increase in personal disorganization. Herbert Goldhamer and Andrew Marshall found that in selected areas in the United States there was no increase in the rate of severe mental illness after the middle of the 19th century (*Psychosis and Civilization*, 1950). Likewise, careful comparisons of mental illness rates in modern urbanized communities and rural folk communities, such as the Hutterites, indicate little difference in the amount of mental illness, but rather differences in the type and form of illness (Joseph W. Eaton and Robert J. Weil, *Culture and Mental Disorders*, 1955).

A variety of approaches have been used to link crime and juvenile delinquency to social organization. Numerous statistical studies initiated by Clifford Shaw and Henry McKay locate the highest incidence of crimes in low socioeconomic census tracts and geographical areas. Changes in homicide rates were found closely associated with the business cycles by Andrew Henry and James Short (*Suicide and Homicide*, 1954). The subculture of criminal and juvenile offenders was extensively studied by McKay, Thrasher, A. Cohen, and L. Ohlin and R. Cloward. As in the case of mental disorder, not only is crime more heavily concentrated in the lower social strata, but the social facilities for avoiding criminal careers are less accessible in lower socioeconomic communities. Sociologists have also studied alcoholism and found

it closely related to the norms and values of particular ethnic subcultures.

7. Social Control and Social Change.—As the various aspects of social organization theory and empirical research matured, sociologists came to recognize the necessity for general synthesis that would explain the basic transformations of society. The study of a society as a whole undergoing transformation has come to be designated as the study of social control or social change. It includes both primitive society undergoing modernization and industrialized societies entering the advanced phases of automation and high-energy technology. The study of social control and social change stands at the frontier of the field of social organization.

The original social organization theorists, both of the economic determinist and the social-value schools, had implicit theories of social change. While these theories remain of importance in the intellectual history of sociology, they are considered to be too narrow and too simple to account for the complexities of social change. Karl Mannheim in *Man and Society in an Age of Reconstruction* (1940) initiated a new phase in the study of social control and social change. His writing reflected the introduction of three important trends. First, economic and technological factors in social change were extended to include the organization of science and of scientific knowledge. Under his influence a sociology of science and a sociology of knowledge developed because of the central importance of science in social change. Sociologists began to study science as an organized institution and profession, the social conditions of which bring about the development of science and the social consequences of science (Bernard Barber, *Science and the Social Order*, 1952). Second, under Mannheim's influence, sociologists broadened their concepts of social stratification to include the study of leadership and the relations of leaders to their followers. The writings of Harold D. Lasswell have been important in directing this trend. The social composition, career experiences, and perspectives of elite groups have come to be seen as important indicators of the direction of social change. (Reinhard Bendix, *The Higher Civil Servants in American Society*, 1949; C. W. Mills and Helen Schneider, *The New Men of Power, America's Labor Leaders*, 1948; Morris Janowitz, *The Professional Soldier*, 1960; Donald R. Matthews, *U.S. Senators and Their World*, 1960). Third, students of social organization have demonstrated interest in social control factors which make possible political democracy (Edward A. Shils, *The Torment of Secrecy*, 1956, and William Kornhauser, *The Politics of Mass Society*, 1959). This perspective has also influenced the study of social control and social change in the new nations.

8. Professional Practice.—Students of social organization have become concerned with the application of these findings to social policy. Traditionally, sociologists limited their work to analysis and diagnosis of social problems and the causes of social and personal disorganization. With the development of the theoretical basis of social organization a broader perspective has emerged. Sociologists have observed that modern society relies heavily on skilled personnel to deal with the problems of social control. It is dominated by professionals and by a trend toward more professionalization.

The study of professions is regarded as a legitimate object of sociological inquiry. Professions are groups of skilled specialists who are organized to regulate the services they perform for society. A distinction can be made between the free professions, like the lawyer and the private doctor, who work independently and directly serve their clients, and the bureaucratic professions, like the schoolteacher who serves in large institutions. The trend is toward the bureaucratic professional, raising new problems of self-regulation. The British social scientists A. M. Carr-Saunders and P. A. Wilson assembled in 1933 the basic documentation of the growth of the profession. In the United States both Talcott Parsons and Everett Hughes developed theoretical concepts for the analysis of professional behaviour. A series of monographs was prepared on the sociological aspects of specific professions, such as professional training, career lines, and internal organization. Among the professions that have been analyzed in some detail are the legal profession, social workers, the military, and the academic.

Sociologists have come to see the professions as a major vehicle for applying the findings of social organization research to the solution of social problems. The Russell Sage Foundation actively stimulated sociological research into the professions. The objectives are, first, to increase the self-awareness of professional groups; second, to supply professional groups with accurate knowledge of the sociological characteristics of their clients and of problems facing their profession; and, third, to assist them in evaluating the effectiveness of the professional services they render.

The application of social organization knowledge centres in the professional schools and professional training. As a result, there has been an increased movement to incorporate sociologists and students of social organization into the faculties of schools of social work, public health, medicine, education, nursing, law, and business. Sociologists also serve in professional agencies and in industry and governmental agencies as research and staff specialists. (Mo. J.)

B. Social Psychology

Social psychology is concerned with behaviour as it is influenced by the actual or implied presence of others. It is believed that the foundations for the characteristically human behaviours of being sympathetic, joking, conforming to expectations, experiencing shame or pride, and forming preferences are developed in the earliest mother-infant relations and subsequently elaborated in relations with others. The understanding of this socialization and the social functions of language and communication is a basic concern of social psychology.

In the study of attitudes the social psychologist is concerned with the processes that influence attitude formation and change. In the study of group process, the social psychologist is concerned with the consequences of attainment of group goals and the role differentiation that attends these adaptations.

In the study of social movements, leadership, interpersonal perception, social rituals, and collective behaviour, the social psychologist builds upon his basic concerns with personality development and group process. He employs experimentation, survey methods, documentary study, and controlled and participant observation. The study of morale, team efficiency, voting, and consumer preference—largely conducted by social psychologists—is one of the most vigorous areas of applied social science. For a further treatment *see* Psychology, Social. (F. L. St.)

C. Human Ecology

Among the many theoretical schemes found in contemporary sociology, one has been prominently concerned with the community. "Human ecology" has drawn upon selected concepts, assumptions, and postulates originally developed in the life sciences in order to describe and explain the structure of human communities. Although the approach was developed primarily by sociologists in the U.S., a direct counterpart emerged in the "social morphology" of the Durkheimian school in France. In fact, ecological thinking can be found in a number of disciplines, and the interests of sociologists working in both the ecological and morphological traditions clearly overlap those of economists, geographers, and anthropologists; indeed, parallels can be found in every area of scholarship that deals with the relations between man and environment.

From its inception, the unique contribution afforded by the sociological version of human ecology has stemmed from its distinctive attack upon certain problems of social organization or structure. First of all, "man" is studied in aggregates, whether large or small, and attention is focused on the structure of relationships between and among aggregates. Secondly, the "environment" is conceived in broad terms, with full appreciation of man's considerable capacity for altering his surroundings. In some instances, the ecologist's interest is in the interconnections between such familiar units as households and firms. These units are regarded as the structural cells or building blocks that make up the community, and the various interactions and linkages among them

have attracted the attention of ecologists concerned with the nature of the community's "internal" structure. At another level of aggregation, certain "external" relations between and among communities are examined, so that whole communities, in their turn, become the building blocks making up still larger systems, *e.g.*, regions and nation-states.

Within sociology, the field has had a rather curious history. The "classical" version of human ecology emerged out of the intellectual ferment generated by a series of naturalistic studies of urban life initiated in the 1920s by R. E. Park, E. W. Burgess, and their students (including R. D. McKenzie and J. A. Quinn). Their curiosity was aroused by the apparent order that somehow developed out of the diverse activities of literally thousands of individuals—individuals who had come from many places, who were largely unknown to each other, and who were each seemingly pursuing disparate and even contradictory ends. In particular, these students of city life became fascinated by the order that was manifested in space.

The original Chicago approach, which had flowered in the 1920s and the early 1930s, underwent a series of searching critical examinations in the late 1930s and the 1940s; most notable among these critiques were those by M. A. Alihan (1938) and W. I. Firey (1947), two works which gave rise to a view that came to be known as "cultural" ecology. But the classical version itself actually did not receive a fully developed statement until 1950, when Quinn's *Human Ecology* provided a synoptic review of the empirical literature, organizing a vast amount of research from many sources within the broad spatial framework sketched earlier by Park.

Space has remained a central concern to ecologists. Nevertheless, it remained for a student of Quinn and McKenzie to broaden the focus of the approach. In his *Human Ecology* (1950), A. H. Hawley defined human ecology as the study of the form and development of the community. Spatial patterns were given close attention, but the principal concern was with the structure of the community, with structure viewed as a "collective adaptation" on the part of a localized population to its total environment.

In addition to organizational configurations observable at a given point in time, ecologists have always shown keen interest in change in the internal structure of the community over time, particularly as it accompanies population growth, and in shifting relations among communities. Only a few of these broad theoretical interests have received detailed empirical treatment. Research in human ecology has been chiefly concerned with such subjects as the spatial distribution of distinctive groups (racial, ethnic, religious, and occupational) within urban areas, the location of manufacturing firms and business establishments, the relationships between workplace and residence, and the territorial division of labour within and among communities.

This brief review should suggest that structural questions are at the heart of human ecology. The traditional focus upon spatial patterns persisted in ecological research although ecological theory has been broadened—at least in the more programmatic statements—to include a systematic treatment of the spatial and temporal manifestations of community structure as simply aspects of that structure. In this view, space and time are no more than dimensions upon which structural patterns may be conveniently observed and measured. At one time, then, the ecological viewpoint was applied chiefly to the internal areal arrangement of the large city; but it has been extended over the years to deal with communities of all sizes and types and to explore their external relations with the outside world. As a consequence, human ecology promises to yield at least one kind of comparative sociology of the community. *See* further ECOLOGY: *Human Ecology*.

D. Demography

Demography, the study of population, is by no means limited to sociologists; it also attracts biologists, geneticists, medical men, public health specialists, biometricians, actuaries, statisticians, and economists. Only in the United States is technical demographic training concentrated in academic departments of sociology; in other parts of the world, demographers are likely to receive their training in one of the other fields.

Demography has been formally defined as "the study of the size, territorial distribution, and composition of population, changes therein, and the components of such changes, which may be identified as natality, mortality, territorial movement (migration), and social mobility (change of status)" (P. M. Hauser and O. D. Duncan, "Overview and Conclusions," in Hauser and Duncan, eds., *The Study of Population: an Inventory and Appraisal*, p. 2, University of Chicago Press, 1959). Each term in the definition denotes a topic that is subject to sociological study, and the following paragraphs set out some of the ways in which the main problems of population are studied.

Demographers deal with population structures and processes. The first three facets of population—size, distribution, and composition—are basically static aspects, in that census enumerations, whether complete or partial (via sampling), yield a "snapshot" as of a given point in time.

(1) Population *size* in relation to the means of subsistence has long been regarded as "the population problem." At least since the days of Malthus, Western writers have attempted to deal with the balance between human numbers and the capacity for their support. Sociological contributions to an understanding of this complex problem have consisted largely of showing how variable elements of culture (such as technology, patterns of social organization, and legal or traditional codes of conduct) affect the balance between population and resources. At least a few sociologists have also been concerned with the implications of population size for patterns of social organization and forms of interaction.

(2) Territorial *distribution* and redistribution of population requires the study of human numbers in relation to area. In its simplest form, the problem resolves into an examination of population density. Sociologists have long been concerned with the distribution of population between rural and urban areas. Urbanization is viewed as a process involving population concentration, the appearance of large and densely settled agglomerations, and a shift in the balance between rural and urban sectors. Explanations of this process have been advanced by sociologists and others, and a number of scholars have also come to be interested in the redistribution of population in and around urban areas; in the U.S., for example, this has given rise to studies of "suburbanization," while in the United Kingdom the emergence of "conurbations" has attracted considerable attention. Again, the components of population change must be examined, for both migration and natural increase (the balance between births and deaths) may bring about changes in the distribution of population between areas. Finally, sociologists have studied the effects of urbanization, the consequences of depopulation of certain areas, and the implications of varying density levels for patterns of social organization and forms of social interaction (*e.g.*, in the city as contrasted with the countryside).

(3) The *composition* of population refers simply to the characteristics of human aggregates, of which any number may be distinguished, ranging from those found in classifications based on purely biological traits such as blood types, through racial and ethnic subdivisions, to such social and economic attributes as marital status and occupation. Questions of population "quality," or the relative predominance of desirable and undesirable physical or social traits, also entail a compositional view of population. There are numerous sociological analyses of the "functional" composition of population, as in studies of the occupational and industrial structure, changes in the labour force, and shifts in the level of formal education; these materials yield basic data on social structure. In addition, "biological" composition is relevant to sociologists. For example, the simple age-sex composition of a population—which reflects past variations in natality, mortality, and migration—sets one of the important conditions to which that population's social organization must adapt. Sociologists have also come to be concerned with the "aging" of population, at least from the standpoint of the social problems it may engender. Changes in age composition are particularly amenable to mathematical analysis (*see* POPULATION: *Knowledge About Population*).

The demographic *components of change* are events that produce

alterations in population size, distribution, or composition. In studies of population size (*e.g.*, growth) or of the redistribution of population between areas, the demographer need only be concerned with natality, mortality, and migration. The population of the world as a whole is, of course, affected only by the balance between births and deaths (natural increase or decrease), but studies of population change in particular parts of the world have always had to take account of the effects of net migration as well. The population of the New World, for example, grew in two ways —by a surplus of births over deaths, and by a surplus of in-migrants over out-migrants. Similarly, analyses of redistribution within countries (*e.g.*, urbanization) have had to establish the levels of natality and mortality in rural and urban areas as well as to determine the number of migrants flowing between them.

The study of changes in population composition is often complicated by the fact that some types of composition are subject to change via "social mobility," as well as by births, deaths, and migratory movements. Changes in age-sex composition in a given period can be fully explained by reference to these last three components, but the marital composition of a population, at least over a brief time span, can obviously be altered considerably without any births, deaths, or migrations if a substantial number of persons marry or secure a divorce. Although not ordinarily so labeled, these individual shifts in status are forms of social mobility in the generic sense suggested in the definition of demography set out above. The four components are taken up below as subjects of sociological study.

(1) *Natality*, or fertility, is of interest in its own right, aside from its importance as a component of population change. Sociologists have been analyzing trends in the level of natality ever since reasonably reliable data on births in particular areas began to become available in the 19th century. Trends in countries with different socioeconomic systems, and with dissimilar cultural traditions, have been compared, as have the trends in rural and urban areas within countries. An area of sociological inquiry into demographic behaviour that has received an enormous amount of attention is that of fertility "differentials"; in addition to variations by place of residence, sociologists have examined birth rates according to such indicators of socioeconomic status as education, occupation, and income, and according to ethnic background and religious affiliation. Much of this research is social-psychological in orientation, entailing a search for the attitudes and values that might predispose individuals toward exercising control over the number and spacing of births.

(2) *Mortality* has proved to be somewhat less interesting to sociologists, despite its importance as a component of population change; this area of research has been left to others—biostatisticians, epidemiologists, and actuaries. The gross trends in the death rate are fairly well known, and some sociological attention has been given to the analysis of rural-urban and socioeconomic differentials in mortality. In particular, "social class" differentials have been subjected to close scrutiny in Great Britain. Falling death rates in underdeveloped areas, particularly after World War II, played a major role in the explosive growth of world population and drew the attention of sociologically oriented demographers to the causes and consequences of variations in mortality.

(3) If mortality has been relatively neglected by sociologists, the same cannot be said for *migration*, or territorial movement. In the modern period, following the emergence of the nation-state, students of migration have come to distinguish between "international" and "internal" movement, with the latter term referring to circulation within politically bounded areas. Sociologists have been interested in the size, direction, and composition of migrant streams, in examining the selectivity of migration, in establishing the causes of migration, and in assessing the consequences of migration for the individual migrant and for the societies and communities of origin and destination. Although internal rural-urban movement drew most sociological attention, other migrant streams have been examined. Within urban areas, for example, residential shifts between inner and outer parts of the built-up area received rather detailed treatment in sociological literature. Finally, motives for migration of all types have been sought by sociologists working within a social-psychological framework.

(4) *Social mobility*, or change of status, has received a great deal of attention by sociologists, who ordinarily use the term to refer to movement between ranked statuses, such as occupations of different prestige. However, only a few mobility problems have been examined from a demographic perspective, *e.g.*, the relation between occupational mobility, on the one hand, and migration and fertility, on the other. Accessions to and separations from the labour force have been long-standing concerns of those who deal with manpower problems, and sophisticated methods have been employed, including the construction of tables of working life, a variant of life table techniques. Still another area is that of the family cycle. The processes of family formation and dissolution (including marriage, divorce, separation, widowhood, etc.) are changes of status that have attracted research attention. Since marriage is an event that can be dated, it is amenable to treatment in terms of the stable population model; as a result, the connection between nuptiality and fertility has been increasingly subjected to mathematically sophisticated treatments, to the benefit of both the sociology of the family and formal demography.

The study of population starts from an intrinsically quantitative base, and the quantities dealt with—human numbers—are vital facts in every field dealing with the human species. Indeed, the utility of population data has come to be widely appreciated by those engaged in policy formulation and decision making, who have made increasing use of demographic work over the decades. In sociology, the fundamental importance of population lies in the impact of demographic factors upon the structure and functioning of community and society. Sociologists have a strategic role to play in providing a fuller understanding of the social determinants of demographic structures and processes.

See also POPULATION; VITAL STATISTICS. (L. F. Sc.)

E. Rural and Urban Sociology

Rural sociology, which developed out of interest in the study of rural life and rural social organization, was recognized as a specialized branch of sociology by 1916, when the meetings of the American Sociological Association were devoted to the central topic of rural sociology. Its counterpart, urban sociology, which developed as a specialization somewhat later out of concern with the sociology of urban phenomena and urban communities, was similarly recognized by the Association in 1925.

Rural Sociology.—Beginning about the middle of the 19th century, with the Industrial Revolution well under way, there was interest in and recognition of the contrasts between rural life and life in the urban industrial centres. However, it was not in Great Britain, where the Industrial Revolution began, but on the continent that an interest developed in the life of rural people. Frédéric Le Play (1879) was among the early students of peasant life with a particular interest in the peasant family. His classic case studies were among the early systematic accounts, although they tended to idealize peasant life based upon the solidarity and stability of the family. Many decades later Carle C. Zimmerman (1935) followed Le Play's family case study approach in his characterization of rural life in problem areas of the United States.

There was also an interest in the social and political aspects of peasant society in Europe. Karl Marx was concerned with the relationship of the peasant to the land and with the development of an agrarian theory consistent with his socialist doctrine. Weber was also concerned with the landholding and communal aspects of peasant life. Thomas and Znaniecki's later study (1918–21) of the Polish peasant in Europe and America is one of the classic studies of peasant society, one in transition from an old established rural culture to a new and urbanized culture. Robert Redfield (1930, 1941) contributed the concept of the "folk society" in contrast to urban society, based upon his studies in Central America. He described the changes in kinship and institutional structures and changes in beliefs and in manners of dress and behaviour as one moved from the isolated village to the urban centre. Oscar Lewis (1951), studying the same villages about two decades later, found tension, factionalism, and other evidence of disorganization.

Another major development in the study of rural society con-

cerned the village. Sir Henry Maine (1871) compared village communities in Eastern and in Western society, distinguishing between types of villages according to the nature of the bonds which held them together. E. Dwight Sanderson's extensive study (1932) of the rural communities around the world was a major contribution to the understanding of the many forms of settlement and structure of rural life and how they were influenced by geographic, economic, and cultural factors. The contrast between closely settled villages, line villages, and scattered farm settlement has been of particular interest to rural sociologists in Europe and in America.

The difference in the structure and content of rural and urban society attracted the interests of sociologists in Europe and in the United States. Thus, rural society, according to Tönnies (1926), is characterized as a society based upon kinship and a commonality of interests (*Gemeinschaft*, community), and the city as a society in which specialized interests dominate (*Gesellschaft*, society). Durkheim (1893) provided another basis of distinction between the small community in which relationships are based upon kinship and homogeneity (mechanical solidarity) from that in which there is a specialization of relationships united through larger institutional structures (organic solidarity). J. H. Kolb (1946), drawing from Cooley, described the greater emphasis upon primary rather than upon secondary groups in rural society. Relationships are more personal, intimate, and face-to-face, as in the rural neighbourhood, in contrast to the more formalized relationship in the larger community. Charles Loomis (1950) drawing from Tönnies attempted to classify groups within rural society along a continuum from the highly *Gemeinschaft* Amish society to the *Gesellschaft*-like government agencies serving rural society.

As the tools and the methods of rural sociology have become more refined, an interest developed in the structure of the rural community. Josiah Galpin's classic study *The Social Anatomy of an Agricultural Community* (1915) led to a definition of the rural community in ecological terms showing the interdependence of the town with its rural hinterland in an area of scattered farmsteads. Kolb (1959) and others in Wisconsin followed that tradition and showed the interdependence not only of the farm population with those living in the towns but also the interdependence of the farm population with the towns of various sizes within an area. For example, the small towns serve as social centres and as the location of the school, or church, or country store, while the larger centres provide more specialized materials, goods, and services for the area. Kolb and his students showed how the neighbourhood based upon local institutions, mutual aid, and interaction had special significance in the American rural scene, in which agricultural villages common in Europe and other countries were absent.

Improved means of transportation and contact in rural areas has led to the structuring of social relationships according to like social and economic interests. The social clique has replaced the neighbourhood in rural society, in which social class becomes the basis of social interaction, rather than proximity or kinship. Social cliques become important in the communication of information, for the control of institutions, and for the socialization of the young. Along with this, the development of cooperatives, farmers' organizations, and agricultural agencies provides more effective channels of information, influence, and services for the farmer. This change in the structure of rural society is described in A. Gallaher's restudy (1961) of a central U.S. community, studied earlier by James West (1945); in A. Vidich and J. Bensman's *Small Town in Mass Society* (1958); in the proceedings of the Rural Sociological Society in 1961, *Our Changing Rural Society;* and in the proceedings of the First World Congress of Rural Sociology, in 1964, published in *Sociologia Ruralis* (1964). While rural communities have struggled to maintain their local institutions and customs, they have become increasingly dependent upon governmental agencies, which in turn have implanted the more universal and secular standards of the larger society upon them.

As urban centres have grown, rural sociologists have become more concerned with settlement patterns around urban centres. They have shown how the fringe areas of urban centres tend to attract people employed in the cities but having rural interests and background. These urban areas attract those interested in cheap land and more space. W. A. Anderson and Olaf Larson (1953) showed how the nature of social participation and social relationships in the fringe areas are influenced by both rural and urban interests and attitudes. Later studies concerned the influence of industrialization upon rural communities. The fringe area beyond the suburbs is one in which rural institutions exist alongside urban developments, usually with little public planning or control. Rural sociologists studying the fringe areas have been more concerned with the changes occurring in rural institutions, while others have been concerned with the problems of delinquency, political attitudes, and governmental structures. O. D. Duncan and A. J. Reiss (1956) compared the characteristics of rural and urban centres of various sizes showing how size and type of centres affect the characteristics of their populations (*see* also *Demography*, above).

Hundreds of descriptive studies of rural communities contributed greatly not only to knowledge of rural life but also to knowledge of social structure and process in general. Studies such as those by Kulp (1935) of the Chinese peasant, T. Fukutake in Japan (1963), C. M. Arensberg and S. T. Kimball in Ireland (1940), S. C. Dube in India (1958), E. C. Banfield in Italy (1958), Donald Pierson in Brazil (1951), Orlando Fals-Borda in Colombia (1955), Horace Miner in French Canada (1939), W. M. Williams in England (1956 and 1963), and others are sources on the values, institutional patterns, social change, and other processes in rural life throughout the world. Anthropologists made many of these studies using a detailed and descriptive approach; rural sociologists tended to investigate more specific issues, such as kinship, institutional patterns, and the processes of change in rural communities. The scattered community studies resulted in few generalizations, however, about social structure and processes in rural life. More systematic studies such as those sponsored by the Bureau of Agricultural Economics of the United States Department of Agriculture during the 1940s under Carl C. Taylor and the study of four regions of Puerto Rico by Julian Steward (1956) described the regional variations in rural life patterns, and in particular their reaction to various agricultural programs.

The selectivity of rural-urban migration and its consequences both for the rural community and for urban areas were among the first topics of concern for rural sociologists in the United States and in Europe. Studies showed, for example, that young people from small farm and tenant families tend to migrate to the cities at high rates. In the United States females migrated at a younger age than did males, and Negroes more than white people. With improved transportation, sons and daughters of families in the less productive rural areas tend to go to the city to work but to maintain their ties to their families for social as well as economic reasons. This pattern is similar to that of the stem family in Europe, described by Le Play, in which family members working in the cities do not sever ties with the home family.

While the characteristics of rural-urban migration in Western society have been described extensively, the underdeveloped countries, as in some parts of Latin America, present new patterns of rural-urban migration. Whole families move and take their rural culture with them. Without status or security on the land, they move to the city in the hope of a better means of subsistence. They inhabit the slum areas mushrooming around the industrial centres and participate little in the life of the city.

The choice of education, occupation, and residence by rural youth is one of the more recent topics of study in rural areas. The interrelationship of occupational and educational aspirations, choice, and attainment as related to spatial and social mobility has been extensively studied in the United States by W. H. Sewell and others. The disadvantaged position of rural youth due to their lack of educational opportunities, lack of knowledge of urban occupations, and the lack of parental and community support has been well documented. Although consolidation and improvement of rural schools helped overcome the disadvantages, a wide gap remains between the potential of rural born and reared youth and their occupational attainments. The proportion of illiterates in underdeveloped societies is, as would be expected, always greater in the rural than in urban areas.

A social psychology of rural life began with the studies of J. M. Williams (1925). Williams showed how the attitudes of rural people in a rural community were influenced by the nature of its environment, its frontier character, and its cultural heritage. The fatalism, skepticism, frugality, and self-reliance are due in part to the uncertainties of the natural forces upon which they depend and to the puritanical tradition from which they come. W. A. Anderson (1947), Edgar Schuler (1938), Howard W. Beers (1941), and others investigated rural persons' attitudes toward rural life, toward agricultural programs, and toward their future, which vary by social class, by tenure, and by other characteristics. Not until the studies by Leland Stott (1939) and Ray Mangus (1948) on the personality characteristics of children and W. H. Sewell (1952) on the socialization of children were studies directed specifically toward personality characteristics and their differences between rural farm and town people. They helped to explode the myth that rural farm children rate higher in what are considered desirable personality traits than those from towns and cities.

Social and technological change began to receive attention by rural sociologists in the 1950s. Charles Hoffer in Michigan (1942), B. Ryan and N. Gross in Iowa (1950), E. Wilkening in North Carolina (1950), H. F. Lionberger in Missouri (1955 and 1957), and C. P. Marsh and A. L. Coleman in Kentucky (1954) were among the first to attempt to study the factors affecting the adoption of innovations such as hybrid corn, improved varieties of seed, fertilizer, and various other techniques. Lionberger (1961) and E. Rogers (1962) attempted to summarize the findings of those studies and contributions to the development of a body of generalizations on the communication of agricultural information and the adoption of innovations in agriculture. Institutionalized sources of information, for example, were found to be most effective for innovations that constitute rather marked changes in farming operations and for persons of middle and upper socioeconomic status. Personal contact of friends, neighbours, and relatives remained most important for farmers with low education and with relatively few contacts outside their own locality. The distinctive characteristics of the "innovator," the "early adopter," and other persons were also described. Studies in other countries by A. W. van den Ban (1958), B. Benvenuti (1961), G. Jones (1960), S. A. Rahim (1961), and F. Fliegel and F. Oliveira (1963) extended to other cultures the generalizations about technological change in agriculture.

Among later developments is the study of social and economic change in underdeveloped areas. Since the majority of the people of underdeveloped areas are rural, the understanding and solution of their problems require knowledge of the structure and cultural features of rural society. Anthropologists have studied the ways in which their integrated social and cultural systems affect receptivity to change and in turn are affected by change. They have pointed out the need for considering the communities and the cultures in these countries as total entities in which there is an interdependence among the technological, economic, social, and psychological factors. Sociologists have been more concerned with the problem of how specific types of change occur and how they are affected by both internal and external forces. The study of community development has been the point of departure for many studies of rural people, their institutions, and programs of change in India, Pakistan, and the Philippines.

In addition to general treatment of the sociology of rural life in the United States (listed in the bibliography) studies sponsored by the U.S. Department of State in Latin America include N. L. Whetten's *Rural Mexico* (1948) and later his *Guatemala: the Land and the People* (1961); Lowry Nelson's *Rural Cuba* (1950); Olen Leonard's *Bolivia, Land, People and Institutions* (1952); Carl C. Taylor's *Rural Life in Argentina* (1948); and T. Lynn Smith's *Brazil: People and Institutions* (1954). Similar studies in other parts of the world have included Irwin Sanders' *Balkan Village* (1949); G. F. Rivera and Robert T. McMillan's *The Rural Philippines* (1952); Arthur F. Raper's *The Japanese Village in Transition* (1950); and Arthur F. Raper and M. Jensen's *Rural Taiwan (Formosa): Problem and Promise* (1953). As the involvement of the United States in World War II and then in reconstruction and development increased during the 1940s and 1950s the assistance of rural sociologists was sought for work in predominantly rural countries. At the same time an interest in rural life and institutions developed in Europe, particularly in the Netherlands under the influence of E. W. Hofstee, who made numerous demographic and sociological studies of rural life, summarized in his *Rural Life and Rural Welfare in the Netherlands* (1957). In England H. E. Bracey's *English Rural Life* (1959) filled a gap in the knowledge of English rural institutions and processes. Peter von Blanckenburg contributed a sociological account of rural life in Europe in his *Einführung in die Agrarsoziologie* (1962). Akshaya R. Desai's *Introduction to Rural Sociology in India* (1953) was the first attempt to bring together materials on the villages and institutions of rural India.

Recent works in the United States emphasize the nature of rural life in a highly urbanized society in which the farm population makes up no more than 7% of the total. Farming is becoming a large-scale business, and rural areas are invaded by city workers, recreation seekers, and conservation interests. In the United States, *Rural Sociology*, the journal of the Rural Sociological Society, completed its 30th year of publication in 1965 and has broadened its coverage to include materials from many countries. Others include *Sociologia Ruralis*, initiated by the European Society of Rural Sociology in 1957; *Quaderni di Sociologia Rurale*, published by the Italian Society for Rural Sociology, beginning in 1961; *Wieś współczesna*, published in Poland since 1956; *Journal of the Pakistan Academy for Rural Development*, since 1959; and the *Revue des Études Rurales*, beginning in 1959.
(E. A. W.)

Urban Sociology.—Sociological interest in urban phenomena began to grow in the latter part of the 19th century when a number of important studies were undertaken in England and the United States. The classic English study of this period was the 17-volume work of Charles Booth, *Life and Labour of the People in London* (1889–1903), an empirical investigation of the state of the poor in that city. The most impressive U.S. study of the period was Adna Weber's investigation of comparative urbanization worldwide.

Systematic development of urban sociology first occurred in the department of sociology at the University of Chicago through the work of Robert E. Park and Ernest W. Burgess and their students, beginning in 1920. Viewing the city as a social laboratory for the investigation of human behaviour, they set a generation of students to investigate problems of human behaviour in the urban environment. The most systematic statement of this approach to investigation, referred to as the Chicago school of urban sociology is found in Robert Park's essay "The City as a Social Laboratory" (1915) and a later one by Louis Wirth, "Urbanism as a Way of Life" (1938). Scott E. W. Bedford's *Readings in Urban Sociology* (1927) and Nels Anderson and Edward C. Lindeman's text, *Urban Sociology* (1928), were the earliest attempts at textbook treatment.

Ways of Viewing Cities.—Cities are social facts of many dimensions, and they have been described and analyzed from many points of view other than the sociological. One way to define the sociological interest in cities is to examine some of the other views.

Men have moralized about cities throughout the history of urban settlement. The social philosopher treats cities (and city life) as objects of human preference, as moral entities. Cities are judged by men as good or bad, as parasitical or fecund entities. To the poet Shelley, "hell is a city much like London," while to the philosopher Aristotle, "the good life can only be lived in the city." The moralist's view of the city presupposes a set of values in terms of which the city is judged as to its desirability or undesirability as a place of human existence. The urban sociologist, on the other hand, seeks a factual description and analysis of cities and city life.

The political scientist views the city as a legal corporation or as a form of government. His concern is with development of urban forms of government, problems of governing the city, and the reshaping or planning of the city through means available to government. The political scientist's view often is close to that of

the moralist since he is concerned with matters of policy, of how government may deal with the problems of urban living.

Historians for the most part are interested in particular cities in history, usually the great cities, their desire being either to illuminate a historical period through the history of a city or to describe cities as history has made them.

The urban geographer and the human ecologist to some extent have shared a point of view in their study of urban phenomena. The urban geographer tends to treat the city as a focal point in the occupation and utilization of the earth by man. Interest in urban phenomena is dictated by an area viewpoint, by such questions as the location, distribution in physical space, and changes in size, location, and internal structure. The city is viewed in terms of the relationships between man and his territorial environment.

The interests of urban sociologists to some extent overlap all of those described above, but urban sociology has a distinct focus as well. The urban sociologist generally views the city as a form of human community in which there are particular ecological forces of integration, in which human beings acquire certain behaviour patterns as a result of association with one another, and in which institutions and forms of social organization give to human life a characteristic aspect called urban. The urban sociologist regards the city and its civilization as a distinctive kind of integration of human activity and as a major source for the initiation and control of social life in societies.

No single frame of reference or theory for the study of urban phenomena characterizes the discipline of urban sociology. There are, rather, three major approaches to the investigation of urban phenomena used in description and analysis. These are the ideal-type community approach, the urban trait-complex approach, and the rural-urban continuum approach; they are sometimes combined.

Ideal-Type Community Approach.—The ideal type is a construct obtained by abstracting the characteristics of an object or institution to their logical extreme and perfection. The ideal-type method is used in urban sociology to describe communities. Usually a number of characteristics describe the ideal type of urban community, but the more characteristics included in the type the less closely do empirical cases of communities approximate it. Some ideal-type approaches posit polar conceptions of communities. As mentioned above, Redfield considered folk and urban societies to represent polar types. He defined the folk society as a small, isolated, nonliterate, homogeneous society whose members have a strong sense of group solidarity. The opposite characteristics define the urban society. Durkheim regarded as polar the society based on mechanical solidarity and that based on organic solidarity; Maine and Tönnies utilized somewhat similar distinctions in their descriptions of forms of human community.

Common to all these ideal-type approaches to human community is use of the types to test hypotheses about human behaviour in a community or society. The ideal form of the community is seen as a source or cause of variation in human behaviour and organization. Redfield, for example, saw the decline in isolation and homogeneity of the community as factors in the secularization and individualization of behaviour of its members.

Trait-Complex Approach.—The trait-complex approach to study of urban communities is closely related to the ideal-type approach, the major difference being that the former uses empirical rather than logically pure attributes in defining a community. The empirical attributes are usually viewed as causally connected. For some sociologists a single variable is seen as the causal or generating variable in the trait complex. P. A. Sorokin and C. C. Zimmerman considered the single generating variable to be occupation: the agricultural occupation defines the rural community, while nonagricultural occupations define other forms of community. The occupational variable is seen in turn as generating other differences among communities. The most important of these usually considered by urban sociologists who use this approach are the size of community, density of settlement, homogeneity-heterogeneity of the population, social differentiation and stratification, mobility of the population, and its system of social interaction. The problem of rural or urban sociology then is to see whether these differences between rural and urban worlds produce differences in social institutions and organizations, cultural and social processes, vital processes, and the psychology of its resident population.

A related approach in urban sociology is that of investigating the extent to which concentration of population tends to give rise to the social phenomenon of the city as a way of life. The two features—concentration of population and the city as a way of life—are allowed to vary independently. The question then raised is, to what extent is the urban way of life limited to an urban population (one concentrated in physical space)? Investigators with this point of view do not see a one-to-one correlation between an urban population and an urban way of life. Concentration of population is seen as giving rise to certain features of social organization that are urban in character. But these features, once established, can be carried beyond the confines of the city so that it is possible to speak of rural populations as highly urbanized.

Rural-Urban Continuum Approach.—The third major approach in urban sociology posits a rural-urban community continuum in which there is a continuous gradation from rural to urban such that all human communities can be placed empirically at some point on the continuum. The definition of rural and urban polar ideal types of communities often implies such a continuum. A major difficulty in this approach is that while a given characteristic of a community may vary from rural to urban, all the characteristics of the community do not vary together with the same degree of urban or rural quality; thus it is difficult to place a given community empirically on a rural-urban continuum.

Factors Studied.—The factors investigated by urban sociologists are chosen from four major sets of community characteristics that define the community as (1) an ecological structure; (2) a unique demographic structure; (3) a characteristic form of social organization; and (4) characteristic forms of social relationships. Each of these characteristics of an urban community defines a focal concern of some urban sociologists.

The human ecologist studies the urban community from the perspective of community structure. The community is defined as the structure of relationships through which a localized population meets its daily requirements. The urban ecologist studies the ways in which the urban community is differentiated and organized, particularly in its spatial organization. He is thus concerned with such problems as the segregation of persons and institutions in space, their concentration and redistribution, and he tries to account for the patterns formed; for example, residential patterns of ethnic groups, business establishments, or occupation groups. At the same time ecologists are interested in the temporal organization of cities, the rhythm and tempo of an urban population. They therefore try to account for such things as the movement of persons between residence and workplace and the patterns of such movement. Finally ecologists are interested in accounting for the distribution of urban communities in space and for the movement of people and the organized relationships that are established among them. They are particularly interested in studying the functional relationships among urban communities and their hinterlands, the exchange relationships among them, and their bases for functional specialization.

Closely related to the interest in ecological organization is the interest in community demographic structure, considered by some ecologists to be only an aspect of the ecological approach. The two most important community aspects investigated in this approach are size and density of settled area. The principal problem for demographic investigators is exploration of the aggregative aspects of the city, such as its population composition and its vital processes of population growth and mobility.

The city often is viewed as a unique form of social organization or social system, the normative organization of the urbanized society and the structures developed for social interaction in cities then becoming the major objects of investigation. Some of the aspects of urban social organization most commonly studied include economic organization, system of social stratification, normative integration, kind and degree of social cohesion among the

residents, and nature of social control. Of particular concern in these investigations is what is uniquely urban about these institutional arrangements and their organization. Are they the peculiar products of urbanism?

Cities also are seen as generating characteristic forms of social relationships. Some sociologists see cities as particularly productive of anonymous and impersonal relationships, persons meeting one another in segmental or highly specialized social roles rather than as full personalities. Collective behaviour in the mass or crowd also is thought of as more distinctively urban. The urban sociologist therefore turns his attention to the kinds of social relationships developed in daily living, the role requirements of an urban dweller, and the ways in which the human personality meets the requirements of urban living. Particular attention also is given to the way in which deviating behaviour is structured in the city, whether it is productive of mental illness, or organized delinquent gang warfare and organized crimes, of dissident social movements, and so on.

Urban v. *Rural*.—Urban sociology is predicated upon the assumption that there are clearly distinguishable differences between urban and rural ways of life finding expression in different technologies, divisions of labour, social organizations and institutions, personalities, and even social problems. Historically the country and the city are viewed as representing different stages of civilized life. Contemporaneously they reflect different modes of social existence. Some sociologists, however, question this assumption, maintaining that the proper study of sociology in this respect is the territorial organization of human groups into communities. Whether or not urban sociology will remain a field in a developing discipline is problematic. There are, however, certain problems dealt with in urban sociology to which the discipline of sociology will undoubtedly recur.

Process of Urbanization.—One of these is the general problem of population distribution and redistribution. An important aspect of population redistribution is the process of urbanization, a process of population concentration such that the ratio of urban people to the total population in a territory increases. Both the size of individual urban centres and the number of urban centres in a territory can increase without urbanization taking place, since only when a larger proportion of the inhabitants come to live in cities is urbanization said to occur. There are four major factors which sociologists use to account for urban growth and urbanization. Their effect has been intensified since the Industrial Revolution of the 19th century.

First of these factors is that of greater productivity per agricultural worker, such that the agricultural system is capable of producing a surplus of food to supply urban populations and also to permit labour to be withdrawn from food production and used in the production of capital goods and services. Technological changes in agricultural production are of course the most important factor changing productivity per agricultural worker. The shift of labor from agricultural to nonagricultural occupations results from the greater income elasticity of demand for industrial as compared with agricultural goods.

The second major factor in the trend to urbanization is a direct consequence of the Industrial Revolution, giving rise as it did to the modern factory system and the industrial city. The invention of efficient techniques for converting energy in fuels and the derivative development of mass production made possible a large number of specialized cities with large populations within an area. Specialization in industrial production leads in fact to high interdependence not only between rural and urban peoples but also among cities; continued industrial production in almost any city depends upon continued production in many other cities.

The increased efficiency of the technology of transportation and communication is a third major factor in urbanization. Because of their specialization and their integration with both a rural and urban hinterland, cities become highly dependent upon trade. Increase in the efficiency of long-distance transportation therefore has a powerful effect in stimulating urban growth, since it makes possible increased trade through access to more and larger markets. Changes in local transport technology are also important in urban growth since they make possible the rapid intracity movement of persons and goods.

The demographic transition accompanying the Industrial Revolution has been a fourth major factor in urban growth. The technology of sanitation and medicine brought with it sharp decrease in mortality, and since countries undergoing urbanization are characterized by high birth rates the result is a phenomenal population growth. The expanding population supplies the urban industrial labour force.

The rate of urbanization has varied both historically and contemporaneously in different countries of the world. Prior to 1800 there were no highly urbanized countries since the cities required large rural populations for their support. From 1850 to 1900 rapid urbanization occurred in countries undergoing the Industrial Revolution, and by the middle of the 20th century the rate of urbanization was seen in many countries to be much faster than in the 19th, because of developing technology. Although highly urbanized areas are generally highly industrial areas, urbanization is not a simple function of industrialization.

Study of Community.—A second major problem area to which the discipline of sociology undoubtedly will recur is the relation of community to territorial location and its relations to the structure of social systems. The principal concern here lies with the study of persons in interaction in territorial locations. The subfields of rural and urban sociology have tended to subvert an interest in the study of community phenomena, so that a comparative community framework of inquiry did not emerge until the middle of the 20th century.

There are three major approaches to the study of community which overlap with the approaches to the field of urban sociology. These may gradually take the place of the earlier concerns with a rural and an urban sociology.

The first of these approaches is based on viewing the community as an ecological system. Ecologists assume that community structure manifests itself in a spatial and a temporal pattern. The ecologist's interest in community centres around generalizations about the structural features of communities and how these change in response to external conditions. The second major approach which has characterized the work of social anthropologists in particular, views the community as a microcosm of the larger social system. Each community is described and analyzed in terms of all of the structural and functional features of the larger society since it is viewed as a territorial microcosm of the larger society. Each community thus is viewed as having a stratification system, a power structure, educational, religious, economic, and political subsystems, and so on. The community viewed as an aspect of structure of all social systems is a third major approach to community study. Populations are investigated in relation to their territorial location with special reference to the social relations that arise between them as a result of territorial location. Sociologists who follow this approach hold that a community system differs from other systems in that locality is a datum in the integration of the system.

When the field of urban sociology emerged within the discipline of sociology, it began as a perspective for viewing all aspects of social life. The city was not only a distinct way of life or form of community but a social laboratory within which all aspects of social life could be examined. With the view that the city was a social laboratory for the investigation of human behaviour, many investigations were carried out within the context of an urban community and the conclusions were thought of as referring to urban phenomena only because of the urban locus. As the field of urban sociology develops, this point of view gradually is being replaced by one based on a comparative sociology of the community.

As these changes occur, many of the problems that were first treated within an urban or rural sociological framework have emerged as separate fields apart from the discipline of urban sociology. Among these are the fields of social stratification, industrial sociology, and human ecology. With the continued emergence of new sociological fields, much of what was traditionally treated within the discipline of urban sociology no longer is rationally included within it.

(A. J. Re.)

III. SOCIOLOGICAL THEORY

1. Introduction.—Sociology as a discipline is defined primarily in terms of a conceptual scheme; its principal organizing focus lies in its theory. This theory, however, clearly stands in an early stage of its development, with only a broad consensus on the principal frame of reference, with uneven degrees of clarity and precision of conceptualization in its various parts, with only spotty formulations of analytical uniformities in the relations among variables, and with uneven achievement of empirical verification of such propositions as we have.

The following condensed review of the main structure of sociological theory is confined to an outline of the definition of major theoretical problem areas and of salient concepts developed in relation to them. It remains mainly at the categorial level of exposition, including the outlining of a number of important classifications. A number of important substantive propositions of general significance that could have been stated are omitted here because of lack of space: to state them with sufficient generality and still make their empirical relevance clear would have entailed an exposition too long for this article.

Furthermore, this article consciously adheres to the terms habitually used by the author, who cannot presume to speak for his profession as a whole. There is as yet no clear-cut consensus on sociological theory as a total scheme, as contrasted with the elements of theory used by many practising sociologists. The elements have been very imperfectly codified. The degree to which the following outline will prove to be accepted for the future can be determined only by a long process of critical work. Considerable modification is to be expected as a matter of course; that there is now a broadly acceptable general framework somewhat along these lines seems to be a reasonable presumption.

2. Theory of Social Systems.—The focus of sociological theory is in the theory of social systems, which may be conceived as the systems organized about—and generated by—processes of interaction among living organisms. Clearly the overwhelming interest is in the interaction of human beings, but certain aspects of sociological theory are continuous over wider reaches of the organic world, thus making contact with the study of animal behaviour. The most distinctively human features of interaction are functions of the presence of language and, hence, communication as a symbolic process. Indeed communication at these levels is the principal content of social process for human beings.

The role of symbolization brings social system theory into particularly close relationship to the theory of culture, which may be thought of as concerned with that aspect of action which is organized about the meanings of cultural patterns and their genesis and conditions of maintenance and change. Sociological and cultural theory are both closely interdependent and interpenetrating over a considerable area, but it seems important to treat them as analytically distinct. Among the social sciences, anthropology, particularly in the United States, is especially concerned with the analysis of culture, and, of course, a variety of other disciplines are concerned with analysis of cultural meanings as such from the point of view of their content, for example, jurisprudence, logic, literary criticism, and others. (*See* further CIVILIZATION AND CULTURE: *Concepts of Civilization and Culture* for distinctions in anthropological and other usage.)

The special significance of culture for the social system, in turn, has an important bearing on the special character of the relationship between the social system and the personality of the individual. By this we mean the organization of the behavioural system linking the biological organism with the social and cultural systems which, from a regulatory point of view, come to constitute the most important parts of the environment in which the person acts. This organization must be consonant with the functional requirements of symbolic interaction, which is accomplished through the internalization of some of the pattern elements of cultural systems, and with the modes of organization of social systems as internalized objects and patterns. The discovery of such internalization of cultural patterns and social objects was one of the most essential conditions of the development of both sociological and personality theory. The most important work converging on this theme was the sociological analysis of Émile Durkheim, the psychology of Sigmund Freud, and the "social psychology" of Charles H. Cooley, G. H. Mead, and W. I. Thomas.

Sociology as a theoretical science does not deal with the whole of the social system as delineated by its mutual relations to the cultural system, the personality, and the organism of the individual —and through the latter to the physical environment. Its concern may be defined as the nature and operation of more or less institutionalized patterns of culture in regulating or controlling, and thereby partially determining, the actions and relationships of individuals. Its special interest is thus on the normative aspect of the social system. The more specifically operative aspects that are distinctively social are ordinarily called economic and political and are the foci of the two prominent social science disciplines carrying those names.

Though analytically distinct, the sociological aspect of social systems is so closely interdependent with the economic and political that the disciplines on each side of this line must be very closely related to one another, so much so that only gradually has it become possible to draw theoretically acceptable distinctions. In the areas ordinarily treated as the concrete concern of economics and political science, the sociologist is more concerned with the institutional framework within which economic and political processes occur and with the internalization of this framework in personalities, whereas the economist and political scientist are more concerned with the specific interplay of "forces" by which economic production, on the one hand, and political decision making, on the other, are brought about.

It goes almost without saying that sociological theory, in its special concern with the normative components of social interaction, attempts to maintain a scientific point of view. The question of the orientation of the sociological observer to these normative components is inherently complex. As scientist he cannot "take them for granted" as directly relevant to him, either in the sense of personal commitment or that of personal rejection. This complex relation, particularly for the study of the observer's own society, is a special case of the very general problem of the relation of the scientific observer to his subject matter.

Like all theories dealing with living systems, the systems with which the sociologist deals are empirically open systems. This has been implied in the stress above on the intimacy of the relations between social and cultural systems, and that between social and personality systems, and again in relation to the biological organism. Such openness does not, however, erase the significance of the analytical distinctions or the empirical boundaries. There is an increasing tendency to treat such issues in terms of a logical model of input-output relationships. "Adjacent" systems thus become mutually dependent for meeting each other's "needs," or functional requirements, through their mutual outputs. The most important historic model of this relation is the economic conception of the division of labour and the mutual dependence resulting from it, which was adapted for sociology above all by Durkheim.

If boundaries are to be maintained, and with them the relevant specification of output to adjacent systems, there must be some modes of normative control over the boundary processes themselves and over the processes internal to the system on which the interchanges of inputs and outputs are dependent. For social systems this system of normative control is precisely what sociological theory attempts to analyze.

The concept social system is an analytical concept which is used on a wide range, from macroscopic to microscopic. At the latter end a small experimental group or a nuclear family can be defined as a social system. In the middle, large formal organizations or associations, local communities, and so on, may be treated as social systems. The concept society is generally used to designate the type of social system which shares a general common culture; often, but not always, language; nationality; and religion; and which is politically organized with reference to a territorial area. But even intersocietal, or more familiarly inter"national," relations can be analyzed as constituting social systems.

3. Structure and Process.—In common with other theoretical schemes in empirical fields, sociological theory divides its con-

cern, on the one hand, between problems of structure and of process and, on the other, between problems of the conditions of stability and of change. The structure of social systems, we have suggested, is composed of patterns of culture. These may be classified under four headings as follows:

(1) Expectations of role-performance for the individual. These are located specifically in contexts of interaction with other individuals and hence cannot be defined without reference to the complementary patterns of expectation for the performance of those with whom the individual of first reference interacts. Any given role is thus, as R. K. Merton has put it, part of a role-set. Since the role-performances of individuals are the sociologically relevant units of interaction process, at this level there must be a network of normative expectations for interacting units. Some degree of "meshing" of such expectations is a condition of minimal stability for such a system.

(2) The organization of plural role-units to constitute collectivities. A collectivity is the aspect of this organization that is relevant to the processes of making decisions to attain goals. It is the political unit of social structure par excellence. The normal individual has plural roles, of course, and is a member of plural collectivities. The concept of collectivity need not as such imply "formal organization," though this is characteristic of the larger and more durable cases. The collectivity is the primary agency of the performance of the social system as a system.

(3) The patterning of rights and obligations among role and collectivity units in relation to norms defining desirable modes of performing functions in the system and avoiding or minimizing dysfunctions. The primary function of these norm components is definition of the situation. The prototype is the legal system in an advanced society, but other components of the system of social control belong in this category. The standards for the definition of legitimate function and for allocation of resources in the system are the focal structures.

(4) The patterning of commitments to values. By values of a social system we mean conceptions of the desirable type of system of reference, for example, a politically organized society. As institutionalized in a social system its values are to a sufficient degree internalized by its members. These values define only the types of system and are not, as such, adequate guides to action because they do not take account of differentiations of function or particularities of situation. Values for a higher-order system are specified to the level of each of its subsystems on the basis of the general rule that, so far as the system is integrated, the pattern tends to remain constant through the various levels, but the content changes to meet the requirements of each subsystem.

All four of these categories are structural in the sense that, over certain ranges of variation, their principal properties may be presumed to be constant, and processes can thus be analyzed relative to them. Empirically, of course, they change, but theoretically the problem of analyzing such change must be distinguished from that of analyzing process in a given structural setting.

The relation of structure to process in social systems generally is mediated through the system of norms (category 3 above). The primarily relevant types of norms in this connection are those that may be called integrative standards. These regulate the evaluation of contributions to the functioning of the system. The most important are solvency as the standard regulating economic productivity, effectiveness as regulating goal attainment, solidarity as regulating the integration of the system, and integrity as regulating the maintenance of the patterns of commitment.

Solvency can serve as an illustration. In a highly differentiated society virtually all units in the social system are enmeshed in the marketplace, on which they are dependent for access to resources and very generally also for mediating relations to the recipients of outputs. There is then the imperative of balancing money expenditures by money income. For the business firm and the normal family household, this is achieved through the money proceeds of operations—the general alternative is liquidation or, for the household, "relief." In the very large category of units to which this version of the standard does not apply, there must be specific ways of securing funds to meet operating expenses, either through contributions or through some form of compulsory levy. So far as such supplementing of money proceeds occurs, it means in general that the unit is "subsidized" from the surplus economic productivity of other units.

The solvency aspect of the operation of economic standards operates within a framework of institutional norms, of which contract and property are the most important parts. Contract is the institutionalization of the establishment of rights and obligations by voluntary agreement among units of the system, individuals or collectivities, *i.e.*, where the relationship is neither ascribed nor compulsory. There are, in turn, two main types of contract: (1) that which establishes directly reciprocal relations between units of essentially the same type, *e.g.*, two firms and (2) the contract of employment, through which the services of an individual are made available to an organization.

The institution of property has historically concerned rights in the use, control, and disposal of physical objects of possession including animals, and on occasion human beings. With the development of market systems, and the more complex ramifications of the monetary medium, financial assets have come increasingly to be the most important part of the property system, a tendency that has been greatly accentuated since the legal development of the corporation.

The institutional framework of contract and property meshes in turn with that of formal organization and the institution of authority, since physical resources, controlled through money alone, and human services, through the money to pay for them and through the contract of employment, are the essential resources for achieving collective goals. For their use to be made effective, however, they must be organized, and authority, with the use of power as a medium, is an essential component of organization in this sense.

Power is involved not only with the use of authority in formal organization but also with the "consent" side of collective action, in selection of leadership and the granting to leadership of authority to act. In turn these elements are related to the exercise of influence—without the coercive sanctions which are the hallmark of power—in mobilizing support for collective action, and in "defining the situation" for those who assume responsibility.

Process in social systems is, then, a matter of interchange of inputs and outputs. These interchanges essentially are processes of communication through which decisions concerning collective action, and the normative framework within which it takes place, are arrived at, and resources are allocated among the units involved.

The essential categories of internal societal output—that is, between subsystems of the social system—are, first, economic production (which is not technological or physical production as such but what economists call "value-added"), which constitutes the fluid resources available; second, collective decisions, which form the basis for the commitment of such resources to specific functions or goals of the subsystems; third, contributions to the integration of these decisions and the corresponding allocations of resources among the subsystems; and, fourth, the normative commitments of the units of the system, ultimately its individual members.

Where social systems are sufficiently differentiated, the genesis and interchange of output products cannot occur without the operation of generalized media of interchange. Again economic phenomena in the concrete sense provide a model in that money is the prototypical case of such a medium of interchange. It is clearly not itself an "output" since it has no "utility." Quite strictly it is a kind of "language" by which the economic meanings of goods and services are coded and transmitted. In the political sphere the corresponding mechanism is power, which is here conceived not simply as capacity to coerce, though coercion is very germane to it, but as capacity to make binding and authoritative decisions and commitments. Not only the power of the "executive" to make binding decisions but also administrative authority and political support through exercise of the franchise belong in the general category of power. We also consider influence, in the socially integrative sense, and the development of normative com-

mitments to be further cases of generalized media for the "control" of social action.

The processes that the sociologist must take into account are not exhausted by the internal interchanges and the mediating mechanisms just reviewed, but must also essentially include interchanges over the boundary of the social system itself with adjacent systems. The essential interchanges are, first, those involving institutional values and the cultural organization of knowledge; second, those involving participants of the system. Empirical knowledge organized and codified at cultural levels is one of the most essential resources for the functioning of social systems, but the output of socially relevant problem statements and the organization of inquiry are equally essential. In relation to the individual the essential input is "motivational commitment" to the performance of social roles. The corresponding output consists of socially meaningful rewards to the individual.

4. Stability and Change.—Both internal interchanges and interchanges across the boundaries of a system can be viewed in either of two ways. On the one hand, it is through these processes that social systems are maintained as going concerns. This is the focus of the problem of the conditions of stability of a system. In sociology as in other theoretical sciences, the problem of these conditions is often formulated in terms of the concept of equilibrium. Equilibrium may be static, concerned with maintaining the system unchanged, or moving, *i.e.*, maintaining an orderly pattern of change. In either case the conception is a device for analyzing the consequences of changes in conditions as "disturbances," which set in motion counteracting forces tending to the restoration of equilibrium. Of course whether or not equilibrium will in fact be restored is for each case an empirical question. The "tendency to equilibrium" is a very generalized hypothesis for the analysis of states of social systems and may or may not be validated for a particular case, or class of cases. Invalidation, however, because of the relative precision of formulation of the problems of the relations between factors of stability and of instability, can be highly useful in throwing light on just what factors account for the instability.

In content the most important sociological concept which bears on the relation between stability and change, between equilibrium and disequilibrium, is that of institutionalization. Institutionalization is the state of relation between the normative patterning of a social system—its values and norms in the senses outlined above —and the other essential components in the determination of the state of such a system. Normative patterns are institutionalized insofar as they are integrated with the nonnormative factors in such a way as to maintain a condition of relative equilibrium. Institutionalization in this sense is not a matter of presence or absence, but of degree. In addition to the "firmness of institutionalization," however, the probability of maintenance of equilibrium is of course a function of the intensity of pressures to change.

Internally the focus of the problem of maintenance of institutionalization lies in the relation between the economic and political interests of units and subsystems of the social system, and the normative factors. The most general concept for discrepancies in this relation is strain. The consequences of strain in turn may be subclassified as involving tendencies to deviance, in the sense that units have interests in violating known and acknowledged normative expectations, and tendencies to conflict, in the sense that the interests of different units or classes of units come to be opposed to each other if there is no adequate mechanism for reconciling conflict. The ultimate in conflict is the polarization of the system in terms of two conflicting sets of units. A third aspect of strain is what, following Durkheim, has been called anomie, which is lack of clarity in the normative "definition of the situation" so that it is not so much a matter of actors not wanting to do what is expected, but not knowing sufficiently concretely what in fact is expected. Finally there may be strain because of uncertainty as to the cultural acceptability of the normative patterns themselves, *i.e.*, in value terms, of their legitimacy. These are all clearly analytical conceptions, and in most concrete cases of strain all four types of components are involved.

These internal foci of strain must be related to the problems of the exogenous conditions of equilibrium. As factors in change, these concern the cultural basis of the values which are institutionalized, the motivational commitments of participants, and the adequacy of the cognitive conceptions of the system and its relation to its environment. If stability is to be maintained, all of these factors must be integrated in terms of procedural mechanisms, by which conflicts and strains can be "handled."

In dealing with change, it is essential to discriminate among a number of types. One pair of such types concern what we may call the "progessive-regressive" axis. This relates to the level of adaptation on which the system stands in relation to its environment. In these terms the focus is on capacity to "cope" with the exigencies of the environment, which in turn means command of resources. The attainment of higher levels of adaptation involves, internally, processes of differentiation in structure, of extension of participation of units in the system—which in one aspect is quantitative growth—and upgrading in the level of expectations, and in the level of generality of the normative structures.

Regressive change is the obverse of this. It is frequently dealt with under the heading of "disorganization," though this term also often designates some of the concomitants of progressive change. The distinction may be a relative matter, in that progressive change always means the disorganization of some subsystems institutionalized at earlier stages of a process. Regressive change involves shrinkage in the resource base and decrease in the fluidity of resources. It involves, frequently, increasing particularity and rigidity, rather than increasing universalism and flexibility, which in our terms is normative downgrading. It often means decrease in scale and breakup of more extensive systems into segments.

The second major axis of social change concerns the pattern of the normative culture itself, notably the value system. Whereas progressive and regressive change concern differences of level along a given directional line, value-change is change of direction of development. The values of a system may orient its functioning more in the direction of concern with and active control over its external environment, or more in that of internal concerns—with the maintenance of harmonious integration or with the integrity of its commitments to a more static pattern of life. It may also vary in terms of whether the main orientation is more instrumental or more concerned with attainment of immediate goal-states. Thus the Communist societies are heavily oriented to attainment of the specifically proclaimed goal of Communism, whereas the "liberal" societies are more concerned with a general pattern of development, without specifically conceived goal-states. Both types, however, are predominantly activistic in orientation to the environment.

All of the factors that in any way influence social action can in principle influence value-change. In the normative aspect of the mechanisms that control the operation of a social system, however, the value system is the highest structural component in the order. Its change constitutes, therefore, a "bottleneck" such that only when other possibilities of adjustment have failed does this pattern itself tend to change. If the change is not to be of a regressive, disorganizing type, then there must be some promulgation, in a more or less "charismatic" manner, of a directional pattern for the change. This may be couched in what we call ideological terms at secular levels, or it may go to the higher orders of cultural orientation we ordinarily call religious.

Since a change in value-pattern is by definition a radical change, it is unlikely that the "promulgation" of new values will come from "official" quarters; *i.e.*, elements who do so by virtue of their institutionalized statuses. The context may or may not, however, be revolutionary in a political sense; charismatic religious movements, for example, have frequently led initially to withdrawal of their adherents from commitment to the existing order rather than to immediate attempts to change it.

However this may be, promulgation of new values is by no means enough. The "promulgators" must not only proclaim a message; they must create a movement of dedicated followers. The task of this movement, very generally, is simplified by a

process sometimes called dedifferentiation, by which many features of the older system that need not be in conflict with the new values are "suppressed" in favour of concentration on the "essentials," *i.e.*, goals that can be "single-mindedly" pursued against serious opposition. Following this there must be a process of progressive institutionalization of the structural components necessary for stability under longer-run and more complex conditions.

5. Concept of Evolution.—It seems likely that a more general theoretical analysis of change in social systems, with special reference to their sociological components, will fall into the framework of the concept of evolution. Earlier attempts in this direction have for the most part been disavowed, but there has been a revival of interest in the problems and increasing recognition of the importance of the questions. No clearly articulated new theory is yet available. It seems clear, however, that it will have to give special consideration to the "modern" type of society, sometimes called "industrial," with its developed monetary and market economy, its bureaucratic and more or less "democratic" polity, its universalistic system of norms, particularly at the legal level. The differences between "capitalistic" and "socialistic" versions will probably prove to be secondary variations. As Max Weber a generation ago said in the introduction to his *The Protestant Ethic and the Spirit of Capitalism*, this "modern" type seems to be of universal-historical significance.

It is also clear that such a theory will have to maintain close articulation with conceptions of the theory of cultural evolution and of biological evolution. Developments in the latter field seem to be such as to make this articulation substantially easier than it would have seemed to be on the basis of the 19th-century biology.

(T. PA.)

IV. METHOD

Throughout his existence man has been observing his own actions and those of his fellows, with the aim of understanding and predicting the behaviour of his social environment. The same aim is held by sociology, the only distinguishing feature of which is the systematic nature of its observations and inferences, codified as its "method" and its "theory." Thus the development of sociology as a social science is coincident with the development of its methods and its theory.

Two obstacles have hindered the development of the social sciences, relative to the natural sciences. In the first place, social phenomena seem fundamentally more complex, that is, less fully determined by a few easily observable factors. This complexity, or relative unpredictability, makes far more difficult the task of identifying relations between causal factors and their consequences. Secondly, experimentation, which has been the most powerful of scientific methods in natural sciences, is severely limited in the social sciences. Only in restricted ways can man carry out experiments on his fellows purely for the sake of knowledge.

Economics has in large part bypassed the problem of complexity by abstracting one element of the functioning of society—valued objects that are produced, exchanged, and consumed—and then assuming that behaviour toward these objects is governed by rational maximization of value. Psychology has in large part bypassed limitations on experimental control by expanding its interests to include animal behaviour, and using animal experimentation where experiments with man are difficult or morally impossible. Sociology has been unable to use either of these approaches to any great degree.

There have been three major stages in the development of sociological methods. It is a curious attribute of sociological method that none have been discarded as new types of data arise; the new techniques are merely added to the existing ones. The major reason is that each newly-developed method is applicable only to a part of the problems which sociologists attack, and the previous methods must still be used for the remaining problems.

The three stages can best be characterized as the use of existing data from natural situations, the purposive collection of data from natural situations, and the control of situations via experiments, to create certain kinds of data not forthcoming in natural situations. Crosscutting this classification is an important distinction between two kinds of data: quantitative, usually obtained through counting of one sort or another, and qualitative, which include no numerical quantities. The more recent developments include a larger component of quantitative data than earlier ones, and a number of quantitative techniques in design and analysis have arisen.

1. Use of Existing Data.—Early research in sociology differed from ordinary experience only in its systematic comparisons. The data were ordinarily obtained from diverse sources: early censuses and precensus government sources; accounts of primitive societies reported by explorers, travelers, and early anthropologists; and other similar observations. Often those observations contained no numerical data but required strategic contrasts and comparisons, as in the work of Herbert Spencer (1820–1903), Ferdinand Tönnies (1855–1936), Max Weber (1864–1920), and William Graham Sumner (1840–1910), and in the early work of Émile Durkheim (1858–1917). The method differs little from the principal methods available to historians today and is still the only method available to contemporary sociologists for most problems requiring historical data.

In a few instances, the data included counts and allowed numerical comparison. Examples occurred in the later work of Durkheim (*Suicide*), who used government statistics to relate suicide rates to various factors in the social structure. Among present-day sociologists, demographers and human ecologists use such data almost exclusively. With the expansion of census data and other counts of socioeconomic events, the potentialities of such data for sociological analysis expanded enormously. For analysis of these data, the methods of statistical analysis discussed under survey research below are applicable; in addition, some methods have been particularly designed for demographic and ecological research.

2. Collection of Data for Sociological Purposes.—As in any science, the exclusive use of data collected for other purposes places a severe limitation on research. Even in the early days of sociology, before 1900, a few researchers, with a particular problem in mind, systematically collected their own data. Frédéric Le Play (1806–82) collected detailed data on family budgets of different types of workers; Charles Booth (1840–1916) used observation and interview to study social life among the working classes of London.

In more recent years, many "community studies" have been carried out by a sociologist or group of sociologists coming into a community as temporary residents, observing, interviewing, and, through the use of detailed field notes, attempting to analyze and then "resynthesize" the social life of the community. One of the best examples of such research is one of the earliest: Robert and Helen Lynd's *Middletown* (1929); another excellent example is William Foote Whyte's *Street Corner Society* (1943). This work is largely qualitative, employing few numbers in the analysis but attempting to lay out the functioning of the community as a system of behaviour. This approach has refused to sacrifice the complexity of a social system for the apparently firm conclusions of quantitative comparisons. As a result, few methodological rules have developed, and the success of the method continues to depend largely upon the researcher's observational skill and his ability to fit together his information so as to mirror the community as a social system. Such work still constitutes a major segment of empirical research in sociology. One of the few methodological treatises for these techniques is Social Science Research Council Bulletin #53, *The Use of Personal Documents in History, Anthropology, and Sociology* (1945).

A very different strategy is employed in survey research, a method that has become widespread. Survey research developed from opinion polling in the 1930s and, like opinion polling, has had the following characteristics, all contrasting with the qualitative studies of social systems discussed above: (1) a focus upon a narrow segment of life, such as voting behaviour, husband-wife relations, consumer behaviour, or attitudes toward public affairs; (2) a systematically selected sample of persons, using the theory of sampling as developed in statistics; (3) a systematic interview

or questionnaire, with a predetermined set of questions; (4) relatively greater emphasis on attitudes than on behaviour; and (5) use of quantitative statistical comparisons in analysis of the data. In choosing this strategy, survey research has gained the important advantage of quantitative evidence, and a resulting precise level of confidence, for its statements. It has largely given up the ability to make statements about a functioning social system, for it samples individuals randomly from this system, and it samples a narrow slice of attitudes or behaviour in interviews. It is likely, however, that the great expansion of applied sociology in recent years has been principally due to the development of survey research. The potential response of a market to a new product, how voters feel about an issue, why families move, who watches various television programs, and a host of similar questions and problems are particularly amenable to survey techniques.

The choice of precision rather than complexity in survey research has led to increasing codification of methods. Research design and sample design, questionnaire construction, coding procedures, and analytical methods have been developed and communicated fully enough to make this class of social research less an art and more a science.

The analytical methods used in survey analysis have several special properties. They are first of all attuned to the state of sociological knowledge and are designed to give evidence for propositions of the sort, "As X increases, Y increases." There is seldom a well-developed theoretical structure for which parameters are to be estimated. Rather, statistical tabulations are ordinarily designed to test the null hypothesis of no relationship between X and Y. Secondly, the variables or attributes may characterize units at one of several levels: individuals, relationships, groups, organizations, social systems. There are special methodological problems at each level (*e.g.*, the problem of aggregation when measurements are on individuals but the proposition refers to organizations) and further problems which arise when the proposition itself refers to two levels. Finally, the attributes which characterize individuals are frequently dichotomies (*e.g.*, vote versus non-vote) or ordered variables, rather than continuous variables. Thus the descriptive statistics developed for continuous variables, such as multiple regression, least squares, and product-moment correlation, have limited applicability in survey analysis. Instead, the less well-developed area of attribute statistics is applicable.

Modifications of survey research have extended its range to the study of organizations and loosely structured social systems (mentioned below).

3. Experimentation.—In some areas of sociology, experimentation is practicable. Numerous studies of small groups have been carried out experimentally: studies of communication patterns, of leadership and morale, of group decision making, of problem solving, of social influence, and a host of others. In contrast, problems which imply long-standing relations, powerful social ties, well-developed norms or status systems, or the interplay of several institutions appear less amenable to experimentation.

As with survey research, codification of techniques has resulted in communicability of method. Statistical techniques of design and analysis, such as analyses of variance, are usable in experimentation; in addition, special observational techniques have been developed to record interactions and other events.

In some cases, research that is a cross between field research and experimentation is possible. In industry, experiments on work groups within the framework of the ongoing social system of the factory have been carried out. As another example, a summer camp was subdivided into two distinct and competing groups. An embedding of experiments within ongoing social systems provides promising possibilities for research.

4. Developments.—Probably the most important development taking place in sociological method is the modification of survey research and statistical analysis for the study of social organizations and social systems. This development applies quantitative rigour to the complex sociological problems of the functioning of a social system. Such modification involves changes in sample design, in questionnaire design, and in analytical methods. Changes in sample design take into account the structure of the organization or system and choose strategic samples at points in that structure. The sample becomes no longer one of individuals, but a sample of relations, or of elements in a structure. Sampling of role relations in a formal organization or "snowball sampling" in a system of informal relations are two types of this sampling.

Changes in questionnaire design complement the sampling changes in two ways: the questionnaire is fitted to the structural location of the individual being interviewed, so that foreman and worker, mother and child, are asked not wholly identical questions, but also complementary questions, and other questions specific to their positions; and questions are asked which refer to specific social relationships and to the social context as felt by the respondent. In these two ways, a questionnaire is designed to measure an element in a social structure rather than an individual considered as a separate entity.

The methods of analysis appropriate to these changes are designed to illuminate the functioning of a system (although in most such analyses, there is no formal model for the system). This involves the use of different descriptive statistics (*e.g.*, intraclass correlation, measures of pair-similarity or pair-complementarity). It also requires a step beyond an ordinary analysis that examines discrete propositions. It requires a synthesis of the separate relationships to mirror the functioning system, a task which, in qualitative studies of communities or other social units, is carried out by the artistry of the observer. In such analysis-and-synthesis, electronic computers play a special role, for the data from the social structure can be stored in a computer's memory in such a way as to preserve the structure. As a consequence, quantitative analysis of the behaviour of the system, rather than of the behaviour of individuals, has become feasible.

5. Special Techniques.—Besides the methods discussed above, there are some special techniques available for certain problems. One of these is known as "sociometric method." All members of a group are asked questions about their relations (actual or desired) with other members, resulting in a complex network of directed relations. Several types of analysis have been carried out with these networks, and, in particular, mathematics appropriate to such networks (matrix algebra, graph theory, and combinatorics) has been used to attack questions of cycle length, clique formation, and others.

A second special technique is used to abstract and classify meaningful content from communications, such as newspapers, books, television, movies. The method, known as "content analysis," makes possible quantitative comparisons of communication content and has been used for such diverse purposes as international images, political campaign issues, advertising themes, and newspaper bias in news presentation.

A final special technique is the use of mathematical models in certain areas of sociology. Such models have been used principally for providing measures of structural properties of social networks or kinship structures, and measures of attitudes or values. In a few cases, a mathematical model has been developed for representing a particular social process, such as occupational mobility or value change. (JA. S. C.)

V. APPLIED SOCIOLOGY

Sociology had increasing application to the solution of practical problems, especially after the second decade of the 20th century. The findings of sociological research have been utilized, particularly in such fields as criminology, social work, education, race relations, planning, government administration, marketing, communication, propaganda, public opinion polling, social psychiatry, industrial relations, and marriage and family counselling. Most sociologists continued in teaching and research activities at universities and colleges.

A number of sociologists, however, utilized their training as professional personnel in fields such as those listed above as well as in the conduct of applied research activities for agencies in these and other fields.

SOCIOLOGY, ANIMAL. The qualitative distinction between the sociology of man and that of other animals is not sharp, but since other animals lag far behind man in the development of abstract thought, in symbolic communication and in cultural institutions, there are very large quantitative differences. The distinctions are by no means absolute, however, and in many relations comparisons are continually being made between the social life of human and nonhuman animals. Indeed, the social life of animals is of interest to many only because of possible comparisons and, more especially, of contrasts with that of man. On the other hand, there are persons for whom the various patterns of behaviour of other animals are of prime importance in their own right. This animal-centred focus is often found among observers

of the group life of animals; it is the dominant attitude among many bird watchers. Yet even the most extreme zoophiles are usually aware of some of the human aspects in the social behaviour of other animals.

Ethologists, zoologists who study the behaviour of animals in their natural environments, claim that man can learn much about himself by objectively observing the societies of other animals. Sociologists, however, often maintain that studies of animal societies have little or no relevance to the study of man's society. The dispute quickens when discussion revolves about "aggression," which ethology regards as inherent to man as well as to other animals. The point is of particular interest because of man's potential for destructiveness and his unique collective expression of aggression, war (see *Agonistic Behaviour*, below).

All too often reports concerning animal sociology are given as though the animals observed were feathered or four-footed men. They are given the thoughts, feelings, and intentions of men. Such anthropomorphic accounts are misleading. Man is the only animal we can know both objectively and subjectively. Except in the figurative sense, no person has ever been a worm, a fish, a snake-in-the-grass, or even an ape. We have no inside information concerning the feelings or the outlook of such animals. The valid interpretation of their behaviour, social behaviour included, is difficult and often impossible except from the point of view of the outsider. This article attempts to be carefully objective. The story remains interesting even under such conditions.

The sociality of animals is of course an outcome of their entire individual repertories of behaviour patterns, which are discussed in the article ANIMAL BEHAVIOUR. This article is divided into the following sections:

I. SOCIAL SYSTEMS

A. GENERAL FEATURES

1. Concepts and Definitions.—A social system is a communication system. It consists of senders and receivers whose roles may be interchangeable, and of signals that produce reliable and consistent responses. Such signals as posturing, facial gesture, utterance, or physical contact provide the binding power of social systems. They will be discussed in the broader treatment of communication that follows.

There are generally three approaches to the study of communication. The first (syntactic) involves the signals themselves, which are studied as physical phenomena; *e.g.*, communicative sounds are analyzed and described in terms of their frequency, amplitude, and timing. The second approach (semantic) involves the meaning of a signal (this path is of course closed to the student of animal communication since one cannot approach the question of meaning on a subjective basis as in human communication studies). The third approach (pragmatic) involves the determination by inference of the significance of a signal to the communicant; it is based on the nature of the receiving animal's response. Models or artificial stimulus inputs can be employed to determine accurately the signal responsible for a particular response.

There are different degrees of sociality, which may be defined either by the amount and kind of information being exchanged or, more conventionally, by the form in space and time of the social system. An aggregation may be distinguished as a group of interacting organisms that associate either because of the existence of some particular environmental circumstance, such as a localized food source, or because organisms merely have temporarily come together by chance. An aggregation has no definite constitution or structure and disbands readily when conditions responsible for the original grouping no longer hold. This is in contrast to a true social organization in which the members of a group actively seek to maintain a relationship. The maintenance of a social relationship indicates some degree of specialization and interdependence by the members of that social system.

At different times in the life cycle of an individual, different forms of sociality may be exhibited. For example, a songbird such as the American robin passes through a fall migratory phase during which it forms large flocks of mixed sexes. In the spring, however, the males become intolerant of one another and maintain and defend territories, on which pairing, mating, and rearing of the young take place. At the end of each breeding season the birds again exhibit a flocking tendency.

2. Types of Interaction.—In the classical sense, social behaviour implies the relationships found within the life cycle of a single species, but under the definition proposed here all types of interaction will receive attention. There are interspecific (between species) as well as intraspecific (within species) relationships.

Interspecific Relations.—These may be conveniently categorized on the type of influence one species has on another. In a neutral relationship no obvious influence is exerted by one species upon another. If both organisms have a negative action on each other, competition obtains. Symbiotic relationships are those in which one or both members of an interaction system derive benefit. If one benefits and the other is unaffected, commensalism exists. If both members of the association benefit, the relation is mutualistic. An amensal system occurs when one organism negatively affects a second without being affected itself. Parasitic or predatory conditions exist when one member benefits to the detriment of the second (*see* also SYMBIOSIS).

Such interspecific systems may be exceedingly complex. Certain small fishes exhibit a "cleaning" symbiosis with other larger species of fishes. The cleaner removes parasites from the host fish, which recognizes the cleaner by its characteristic movement and colour markings. Some other fishes have evolved colour and behaviour mimicry and resemble cleaners. These fishes are, however, predators that bite small pieces from the host fishes.

A discussion of social interaction includes a consideration of ecological communities, natural associations of plants and animals forming an interdependent entity in nature. Leaving aside the plant-animal relationships, the investigation of animal populations alone has yielded many insights into the interdependency of living things. It has been demonstrated that the survival of a given population depends on the maintenance of an optimal density or group size. The rate of development of sea urchin eggs is a function of their density: there is an optimal group size above and below which the rate of cleavage of the developing egg is affected

BY COURTESY OF A. L. COHEN

Slime molds transforming (left) from individual cells to (centre) "slug" stage and finally (right) to a fruiting body may represent a primitive level of sociality

adversely. It is equally interesting to note that members of a given population may condition the environment in such a manner as to promote survival of other members. This type of conditioning is apparent in colonies of one-celled organisms (bacteria, protozoa) as well as in mammals. An active rat colony is continually excavating burrows that serve for several generations. A definite survival advantage is conferred on young rats that mature in a colony containing a number of ready-made tunnels. The burrow is an artifact passed on to future generations in a manner analogous to the passage of artifacts within a human cultural system.

Such observations gave rise to the formulation of the principle of proto-cooperation. This concept implies the existence of a nonspecific, derived mutual benefit from the interaction of organisms which is basic to the evolution of any ecological community. On the other hand, any population of organisms is necessarily dependent on a certain level of available resources. Ultimately, this means that a spatially restricted population must be limited in its growth by the negative interaction of its members who compete for these resources. These biological ideas influenced social thought through the philosophic writings of Herbert Spencer, whose interpretation of Darwinism promoted competition ("survival of the fittest") as the dominant evolutionary force, and through the social idealism of P. A. Kropotkin, whose concept of mutual aid emphasized cooperation. Both are extreme views of nature, whose reality is neither total savagery nor complete solicitude. Behavioural mechanisms of a competitive nature exist side by side with those mechanisms generally termed beneficial or cooperative. This idea will subsequently be dealt with at greater length.

Intraspecific relationships probably began with the slime molds, which bridge the gap between independent existence and multicellularity. Multicellular organisms, interdependencies of cells, led imperceptibly to social organizations, interdependencies of individuals. The cellular slime molds exhibit a life cycle that includes a free-living and a colonial stage. During the free-living stage these animals behave as amoebas, feeding by means of pseudopods and reproducing by division. At high population densities the amoebas aggregate into a sluglike form that moves as a unit. This interdependent mass of amoebas is formed by means of chemical communication; the "slug" produces a substance known as acrasin, which induces free amoebas to follow up the gradient and add themselves to the group. Within the mass of cells, differentiation and specialization occur. These primitive forms are of interest to animal sociology in that their "slugs" may be the first evolutionary attempts leading to multicellular organisms. It has been proposed that most multicellular plants arose from such a process of aggregation but that most multicellular animals arose from the subdivision of a single-celled multinucleated organism. This may in part explain why a multicellular animal body achieves complex levels of diversity and interdependence among organ systems and tissues far beyond that displayed by plants. If higher plants arose from clumping of individual cells, this process may well have set initial limits on the degrees of tissue diversity and interdependence.

Reproduction plays an important role in the establishment of social relationships. Organisms such as the amoeba, which reproduce asexually by simple binary fission, are totally independent of others of their kind for reproduction. Other unicellular organisms such as paramecia are dependent to a degree on each other to sustain reproduction. A species of *Paramecium* may include several different strains that must exchange genetic material at some specified interval following a series of asexual divisions. This process of exchange of genetic material is known as conjugation, one of the many forms of reproductive interdependence that has evolved in the animal kingdom. Sexual reproduction is of nearly universal occurrence among multicellular animals. Special sex cells (egg and sperm), containing one-half of the normal genetic material, are produced. These cells, or gametes, unite to form a zygote with the restored amount of genetic material. The zygote then undergoes a series of divisions and becomes a multicellular organism. (*See* also REPRODUCTION.)

Sexual reproduction has come about by the evolution of interdependence resulting from a differentiation of roles. Unless environmental variables regulate gamete discharge completely (as occurs among fishes), selection favours the evolution of a communication system whereby the activities of the reproducing pair become synchronized to ensure continuation of the species.

Parental care of the eggs or young has evolved independently in many animal taxa and further fosters socialization, in this case a parent-young (or parent-egg) interaction system. Three general types of families may be recognized, based on studies of fish: a father family, in which the eggs or young are defended by the male alone; a mother family, in which the female leads, nourishes and protects the young; and finally the parental family, a combination, in varying degrees, of both types of parental care throughout the rearing of young.

More complex types of intraspecific sociality include groups of animals of both sexes and of several age classes. If these groups are not simply aggregations, they show some cohesion over a period of time and tend to coordinate their activities. Such groups may form by two general methods of recruitment: internal, by birth, or external, from genetically unrelated individuals. Family bands tend to be interdependent, cohesive, and closed to external recruitment; typically they consist of several generations of both sexes. Herds, schools, and flocks are generally formed by both internal and external recruitment; a herd, for example, may be a temporary grouping actually composed of family subgroups.

The maintenance of cohesion in social groupings involves several basic mechanisms. Synchronization of movements or activities is, in part, an aspect of social facilitation, the tendency for animals in groups to exhibit an intensity of behaviour different from that they show in isolation. For example, individual chickens will eat more food when grouped than when isolated. Flocking in birds or schooling in fishes results in part from instinctive mechanisms promoting a mass duplication of activities such as moving, settling, and feeding. Cohesion is also facilitated by a following response which involves a tendency to follow a moving member of the group. A member that initiates the movement regularly is a leader. Quite often in such mass movements as fish schools, loose bird flocks, or locust swarms, a true leader is lacking and the leading edge of the group is in constant flux. On the other hand, herds of red deer or horses often have a leader that consistently initiates movement within the group.

Cohesive social groupings involve an interchange of stimuli that promote group integration. Special grooming ceremonies among mammals and among birds permit an exchange of stimulti that maintains contact and familiarity. Special sounds, such as the call notes of flocking birds or choruses of frogs and crickets, serve as attractant stimuli necessary to group integration. Even aggression, popularly thought of as detrimental to group formation, has a definite and well-established social function. Aggression between members of a species (intraspecific aggression) serves to (1) promote group integrity by excluding aliens; (2) strengthen pair bonds by excluding other potential mates; and (3) encourage spacing, thus minimizing competition for available food and shelter. Interspecies aggression, on the other hand, establishes food webs of predators and competitors. Within a social group, aggression is generally controlled by the maintenance of a dominance hierarchy.

B. Methods of Communication

A social signal is derived from some neutral source that was originally not solely communicatory in function. Natural selection favours the enhancement of such a neutral source if it conveys some information. Most visual displays originated from several neutral sources. For example, before moving, most animals have a set of preparatory activities termed intention movements. A bird crouches and then raises its wings before flying. These simple preparatory movements may become selected for in a population if there exists some advantage for the group to know the intention of the sender. A simple crouch may later be used in response to a certain social situation. Such behaviour may undergo natural selection until the population develops a ritualized bowing motion.

In a similar manner responses of the autonomic nervous system to various stimulus situations may be selected for—to produce ritualized secretion by skin glands, ritualized defecation or urination, and ritualized breathing or vocalization. The process of ritualization involves an enhancement of the original movement, sound, odour, or posture. Elaborate structures and colour patterns are all derived from the action of natural selection to produce a more conspicuous effect. In some cases a movement may undergo selection until it is so stereotyped that its origin becomes obscured.

1. Chemical Signals.—Since the chemical sense is one of the most widespread sensory modalities in the animal kingdom, it is not surprising that chemical communication is an all-pervading phenomenon. Chemical particles are detected by a variety of sensory devices in different animals.

Lower animals, such as protozoans and flatworms, detect chemical changes in their environment by means of osmotic fluctuations. Social insects, such as ants, bees, and termites, depend on chemical

RUSS KINNE FROM PHOTO RESEARCHERS

PERSONAL CONTACT OF GROOMING BETWEEN BABOONS HELPS MAINTAIN STRONG SOCIAL BONDS

glandular exudates that guide the colony (*see* Social Insects). Very often volatile chemicals called scents are used to attract sexual partners. The male silkworm moth responds selectively to the airborne particles secreted by a virgin female of its species; he tends to fly upwind on perceiving the particles and, by seeking out the greatest intensity, eventually finds the female.

Vertebrates, which have taste buds and nostrils, can detect flavours and odours (actually chemical particles) that can convey a variety of meanings. Dogs and wolves stake out territories by urinating or defecating at "scent posts." When a member of a minnow school is injured or killed, special glands in the skin release a substance termed *schreckstoff* ("alarm-substance") which warns other minnows of danger. Sharks may be driven into a feeding frenzy when they detect blood in the water.

2. Visual Cues.—Visual signals require a photoreceptive sense organ. Unlike chemical signals, visual signals are direct, rapid, and localized. Such signals are produced in nocturnal insects or deep-sea fishes by bioluminescent organs. In day-active animals visual signals are produced by stereotyped movements or postures that are easily recognized. Often colours and special structures, such as crests or manes, further enhance the display movement. Fishes and octopuses possess special cells known as chromato-

Chemical communication binds (left) termites in a rigid caste colony and (right) provides scent trails for processionary caterpillars

phores that allow rapid colour changes that convey a subtle form of visual communication. Seasonal plumage or hair colour changes in birds and mammals achieve similar effects.

The use of models in the experimental determination of visual communication systems in birds and fishes has met with much success. Through such techniques it has been found that animals often respond to a very small but relevant portion of the total visual pattern that humans perceive. For example, a young herring gull pecks at the bill of its parent and thus induces it to regurgitate food, which is then eaten by the young bird. Studies of the pecking response, using cardboard models, show that the head shape and bill structure have little to do with releasing the response by the young. The chicks respond best to an object that resembles a long, thin stick striped at the top with red bands on a light background; such an artifact that produces a greater response than a natural stimulus is said to be a supernormal stimulus for releasing a response. In this example, the striped stick must be held vertically near the chick and moved slightly to produce an optimum pecking response. The model is really an exaggeration of the relevant stimuli present in an adult gull's bill, a red spot on the tip of the lower mandible that serves to release the pecking response. From the chicks low level of view the bill resembles a long, thin object in the same manner that the supernormal stimulus does.

Just as certain animals respond to a small part of the total available sensory input, others respond to a complex of stimulus configurations. Many birds, fish, and mammals have graded displays that change with the motivational state of the sender. For example, in the chaffinch, as the tendency for attack increases the bird shows a progressive raising of the wings and an increased flexing of the legs. Cats may show a graded series of postures from a crouch with flattened ears and slitted eyes to a standing posture with erect ears and open eyes. All intermediate variations indicate mixtures of tendencies to attack and flee. The more complex and subtle the social interaction the more highly graded is the signalling mechanism, indicating that learning has probably played an important role in associating the appropriate responses with a given expression. A complex set of sense organs is required for perceiving the relevant stimuli and a complex nervous system is necessary for associating the signals with the responses.

3. Sounds.—Auditory communication is very common in terrestrial vertebrates and invertebrates. It has great importance for aquatic vertebrates such as fishes and mammals. The chief advantage of auditory communication over visual communication is that it can be performed out of the direct line of sight of another animal. As with visual communication, auditory communication can give information concerning the sex, age, species, motivational state, and individual identity of the sender. Sound messages can promote aggregation (mating song of crickets) or dispersion (distress call of birds). The use of the tape recorder and sound spectrograph has permitted accurate analyses and physical descriptions of auditory signals as well as experimental verification of the role of sound in animal communication.

4. Contact.—Tactile communication is the direct contact between two individuals. A contact ceremony is often quite ritualized in that certain areas of the body are primarily involved in an initial contact. A set of stereotyped contact postures are developed; in mammals these generally include naso-anal, naso-nasal, and naso-genital contact patterns. Chemical, visual, auditory, and tactile communication may all be involved simultaneously.

See also PSYCHOLOGY, COMPARATIVE: *Man Compared with the Lower Animals* for a survey discussion of aspects related to communication.

II. INTERSPECIFIC SOCIALITY

As indicated earlier, animals occur in communities, predictable species complexes within habitats characterized by specific climatic, geochemical, and botanical features. Members of a community are continually interacting and thus exchanging information. By their interaction, community members exert selective pressures on each other that confer a survival value to certain characteristics within a given population.

1. Predator and Prey.—A predator and its prey form a very special case of interspecific communication. A predator is faced with the problem of locating appropriate prey and, conversely, a prey is faced with detecting a predator and either escaping or defending itself. Occasionally, the most conspicuous anatomical features of a species are the direct result of selection for defense against predators. The armadillos are a case in point. The most heavily armoured armadillos (*Tolypeutes*) roll into a ball and thus present an impregnable sphere to the predator. The other genera behave differently when attacked. The *Chlamyphorus-Chaetophractus* complex, as well as the genus *Priodontes*, has flat carapaces that provide adequate protection when the animals dig a shallow depression into the ground to avoid predators. The genus *Dasypus*, lightly armoured and not so well adapted for digging relies on its long legs and flees into dense vegetation, where its plates serve to ward off rough branches. In the family of armadillos, then, the behavioural traits of rolling into a ball, digging into the ground, and running to cover are differentially correlated with differences in the thickness of the armour, the length of claws, and the length of limbs. All these conspicuous features have resulted from selective pressures exerted by predators.

Both interspecific and intraspecific sociality may be promoted by the action of predators. Colonial life permits many sense organs to be employed in the detection of predators. If warning cries are selected for, many colony members, without actually perceiving a predator, can be made aware of its presence. This is the protection afforded a flock or a school. Furthermore, sudden scattering of flock or school members confuses the predator, imparing its chances for a successful kill.

Solitary animals frequently evolve cryptic postures or camouflage patterns in response to the selective pressures exerted by predators. Freezing in place is a response that renders prey less conspicuous because of its immobility. Camouflage aids concealment because either the markings blend with the background or the patterns of line and colour break up the outline of the animal.

2. Model and Mimic.—If an animal is distasteful or possesses a potent weapon such as a sting, it is generally avoided by experienced predators. Such unpleasant prey often assumes a striking colour or a conspicuous pattern (warning colours). Species

resembling noxious types with warning coloration share the immunity from predation conferred on the noxious species.

Such model-mimic systems need not, however, evolve only from the discrimination practised by a predator. In the case of cleaning symbiosis discussed previously, the host fish and the cleaner fish have evolved elaborate interspecific communication systems. Communication involves special soliciting postures by the host and specific coloration and movement patterns by the cleaner. In several cases, a small predatory fish that resembles a cleaning species can approach a prey fish and feed at least once with impunity. The hosts, however, soon learn to discriminate between the true cleaner and the mimic predator, but a definite selective pressure exists to favour the maintenance of the mimic since naive host fish can still be approached by it. This points up an unsolved problem with model-mimic systems: if the mimic achieves a population density sufficient to cause the selecting species to discriminate between the model and the mimic, the mimic could be exterminated. (*See* also MIMICRY.)

3. Competitors.—Within a natural community, different species compete for some resource in restricted supply. Selection tends to reduce competition by producing populations that utilize the available resources in specialized ways, thus producing diversity among members of the same community. In fact, members of the same species compete with one another more strongly than they do with members of different species. The wood warblers of the eastern United States provide an example of such specialization: different species found in the same community tend to forage in different zones of the trees. Some, like the Cape May warbler, forage in the crowns of trees; others, like the myrtle warbler, forage in the lower limbs. The effect is reduction of interspecific competition.

A definite dominance order may exist among several species in a community that compete for a single limited resource. In arid regions of southwestern California, small mammals of the chaparral community compete for sources of water. During the dry season the succulent prickly pear cactus is the common source of water for several rodent species. The desert wood rat nests in prickly pear patches and aggressively defends them against other wood rats and other rodent species including the agile kangaroo rat and several species of deer mice. A definite limit is placed on the population density of the associated mammalian species by means of the dominant status that the wood rat holds.

4. Mixed Groups.—Numerous vertebrate species form social systems that exhibit some cohesion and permanence over time. These social structures include mixed flocks of birds, mixed herds of hoofed mammals, and mixed schools of fishes. Bird flocks of mixed species have received the most study.

In the New World tropics honeycreepers, blue tanagers, and green tanagers typically form mixed flocks. Such social groupings have selective advantages including an enhanced ability to detect predators and to locate food. Within a mixed flock, several species are nuclear in that they consistently form a flocking association, while other species may be occasional joiners and are hence considered attendant. The nuclear species are generally of two types, termed passive and active. The passive species exhibit pronounced gregariousness and tolerate the proximity of the active, nuclear species that are motivated to join and synchronize their movements with the passive nuclear species. Because of the survivorship benefits resulting from mixed flocking, selection favours seasonal or permanent plumage changes that reduce conspicuous differences between nuclear species in mixed flocks.

III. INTRASPECIFIC SOCIALITY

A. Reproductive Association

Social groups may arise from the processes of reproduction. Sexual behaviour demands the formation of mass mating groups, temporary or permanent pair bonds, leks, or harems. Parental care results in the various forms of family groups. The progeny themselves may constitute a social group. As a result of asexual reproduction in protozoa, the newly formed individuals may constitute an aggregation because of the limited nature of suitable habitat. Young spiders emerging from an egg case may constitute a temporary aggregation because many eggs are laid in one spot. On the other hand, complex, cohesive organizations may arise from family groups as a result of a division of labour and a sustained interchange of positive stimuli among the group members. The complex insect social organizations of the Hymenoptera and termites are derived from family groups with a permanent division of labour based on a caste system (see *Insect Colonies*, below).

1. Mating and Courtship.—Certain environmental cues serve as stimuli to prepare the sexes for reproduction. In the temperate zone the reproductive periods are cyclic and correlated with seasonal climatic changes. Increasing light with the onset of spring can serve to stimulate the hypothalamic part of the brain via the optic nerves in ferrets and many species of birds. Such hypothalamic stimulation results ultimately in the production of pituitary hormones that induce production of mature sex cells. Light functions as a necessary stimulus to reproduction in cattle and sheep, but here the shorter day lengths of late summer rather than the longer day lengths of spring are the trigger.

Environmental stimuli may be quite precise in their effects. Palolo worms spawn annually in the lagoons of the South Pacific only in response to the last quarter of the October–November moon. Such synchronized spawning involves virtually the whole adult population of these marine worms. They swim to the surface in writhing masses. The posterior segments containing the sex organs are detached from the body and subsequently discharge their gametes into the water. In habitats such as the desert, selection has favoured very restricted stimulus inputs as triggering mechanisms. Arid-adapted birds such as the zebra finch are primed to respond to rainfall by an almost immediate onset of courtship, nest building, and sexual behaviour. Such an adaptation permits the rearing phase to follow the growth and seed production of arid-adapted plants, which are especially vital as a food source.

Environmental control of reproduction is stressed in the cases above, but in addition most vertebrates and all terrestrial-breeding invertebrates are generally dependent on an interchange of stimuli between the pair to promote mating. The communication system leading to the sexual act is termed courtship.

Courtship displays serve to attract mates, ensure species specificity in mating, arouse the mate, and synchronize activity. To guarantee species specificity, the form of the display and movement patterns tend to be unique. Often a chain reaction of stimuli is involved in which a signal from the male triggers a signal from the female, which in turn serves as the next initiatory stimuli for the male, and so on. Many courtship movements reflect an ambivalence that indicates origin from intention activities caused by the simultaneous arousal of attack, escape, and sexual drives within the interacting animals (*see* COURTSHIP, ANIMAL).

Courtship and related activities sustain physiological arousal demanded of reproductive activities. In a bird such as the ring dove courtship activities stimulate the pituitary to secrete follicle-stimulating hormone, which acts on the ovary to produce estrogens. Estrogens produce a sensitization of the brood patch on the breast of the bird. Brood-patch sensitization promotes nest-building activity, which in turn stimulates ovulation and subsequent progesterone secretion by the ovary. Finally, progesterone further sensitizes the brood patch and promotes broodiness, which leads the female to incubate the eggs.

Courtship and mating behaviour involve pair formation. The pairing relationship may be brief and terminated at the conclusion of the sex act, or it may involve a long-term interchange of stimuli between the partners, a pair bond. In pair bonds both parents are generally involved in the care of the eggs and young.

2. Mating Systems.—Several different mating systems can be distinguished by consideration of the numbers and sex classes of the animals involved and the duration of the pair bond. Promiscuity is a common form of mating behaviour in which no permanent pair bonds are formed. Monogamy exists when permanent pair bonding occurs. Polygyny involves one male and several females in the mating system. Two variations, lek breeding and harem formation, may be defined. A lek system involves a group of males that assemble on a traditional breeding ground. A dominance order is established with one aggressive male attracting visit-

ing females and performing most of the mating. Lek breeding has been noted in birds such as the sage grouse and cock-of-the-rock and in mammals such as the Uganda kob. In the harem system, a male defends a female group with which he has an exclusive mating right. Polyandry, a mating system involving one female and several males, is relatively rare; it occurs temporarily within certain primate societies such as that of the howler monkey.

3. Family Groups.—Parental care is well developed in some species of insects, crustaceans, and vertebrates. The parent and the young or egg clutch form a system that involves a constant interchange of stimuli. Such an interaction system is exemplified by the army ant *Eciton hamatum*. The eggs of a new brood exude substances that render them attractive to the workers. As a result the eggs are licked and carried continuously during the nomadic phase of the ants' activities. As the eggs develop, first into larvae and then into pupae, they continue to provide a focus of attention for the workers. During the pupal phase the army ant troop settles in a protected area until the pupae hatch. The newly emergent young workers trigger a renewal of wandering activity in the ant troop and the newly laid eggs for the subsequent brood are again taken up and transported during the wandering phase of the troop's life. Thus the alternation between the stationary and wandering phases of the army ant is a direct function of the stage of development of the brood.

In a similar fashion a mother rat and her brood portray a communication system of interdependence. The newborn rat is dependent on appropriate stimuli from the female for its initial development. The rat pups are attractive to the female, and at birth she licks the amniotic fluid and blood from their bodies. Lactation is sustained by the tactile stimuli of the nursing young. At the same time the turgid organs are relieved by the nursing activities of the young. The young rat will not exhibit a normal elimination reflex unless the female licks the anal-genital area. One cannot avoid the conclusion that the mother-young relationship involves an interchange of mutually interdependent stimuli.

B. Early Experience and Socialization

Research has established the importance of the social environment to the development of behaviour during maturation. The classical technique has been the isolation experiment, in which young animals are deprived of the animate and inanimate stimuli normally encountered in the course of their development in nature. Several important generalizations relevant to social behaviour have been derived from these experiments. These include the concept of a critical period, during which socialization takes place, and a realization that species differ in the amount and quality of stimuli necessary to produce normal adult behaviour.

1. Critical Period.—Imprinting is a type of rapid learning that occurs during a discrete period in the life of an animal. The classical examples of imprinting were derived from studies of ducks and geese. In a typical case of imprinting, a young gosling hatches and within 24 hours is capable of following the parent. During the process of following the parent, the gosling learns the visual cues and calls of the adult bird and can discriminate between its own parent and a strange adult goose. The process of imprinting on adult characters carries over into the young bird's adult life. Not only are the individual stimulus patterns of the parent learned but also the general stimulus configuration of a goose. Thus, the young gosling imprinted on its parent will in adult life seek out geese of its own species.

Goslings raised by different species of geese or by man will imprint on the foster parent. Such imprinting is virtually irreversible and the young bird when it reaches maturity will select its foster parent type as a sexual companion. Imprinting can take place only during a critical period of a few hours' duration. If imprinting by means of following a parent or foster parent is denied the young bird, it will be incapable of forming permanent adult liaisons with members of its own species.

A similar phenomenon is encountered in hoofed mammals in which the young exhibit a following response directed toward the parent. In the case of sheep, the mother is maximally receptive to learning the odour of her lamb during the first few hours after its birth. The time interval is critical, because if the ewe is denied access to the lamb for several hours after its birth and then is confronted with the lamb she is prone to refuse it. The lamb apparently learns the visual, chemical, and auditory characteristics of the ewe over a period of several days.

In mammals such as the dog which are helpless for some time after birth, there are longer periods of adjustment to society. Social behaviour develops from the point of full awareness to final weaning. Puppies reared in isolation never form close attachments with humans or other dogs (*see* Dog: *Development of Behaviour*).

Some species such as the golden hamster are dependent on a minimal stimulus input for the

REPRODUCTIVE ASSOCIATIONS: (ABOVE) A HAREM OF SEA LIONS; (RIGHT) A FAMILY OF MULE DEER WITH AN EXPERIENCED DOE LEADING THE GROUP; (BELOW) THREE SAGE GROUSE COCKS IN COURTSHIP DISPLAY BEFORE ONE HEN ON A STRUTTING GROUND

normal development of adult social behaviour. Hamsters removed from the nest at three days of age and reared in isolation by artificial feeding and incubation techniques appear little affected in their development of adult patterns of aggressive, courtship, and sexual behaviour.

2. Effect of Social Deprivation.—Higher primates, including man, are strongly dependent on a social milieu for normal development. A young rhesus monkey reared in total isolation from other monkeys, with only a crude model consisting of a nursing bottle fixed to an upright wire body with a false face, learns to associate the model with food and with protection from frightening stimuli. When two models are supplied to the monkey, one with a wire body and the other covered with cloth, the infant chooses the cloth model over the wire model. This preference is shown even though the infant can feed only off the wire model. The young seeks a certain type of tactile stimulation from the model that becomes associated with comfort.

Infant monkeys raised with models exhibit abnormal behaviour when placed in groups. As juveniles they show a tendency to withdraw and rarely exhibit normal sexual behaviour. If, however, such isolated young are allowed to form play groups with other isolated infants at about six months of age, their adult behaviour is not so deviant. Play-group therapy initiated after one year of age, however, is less effective in promoting normal social behaviour.

Likewise, children reared in foundling homes where a minimum of social stimuli are present exhibit behavioural pathologies of an irreversible nature. Motor development as well as intellectual development is slow. After three years of age such institutionalized children are generally hopelessly retarded. It appears that infant higher primates have periods of socialization during which social stimuli are imperative for initiating learning processes that carry over into adult social life. (*See* PRIMATES: *Socialization.*)

Periods of socialization generally occur during the transition phases between the infant stage and juvenile stage of maturation. In higher vertebrates such transition phases are characterized by play behaviour. In play behaviour no ultimate resolution occurs, but rather components of functional adult patterns appear. Incipient food seeking, fighting, mating, and flight are displayed. Play groups, including littermates or the parent, are a source of the stimuli necessary for normal maturation (*see* PLAY, ANIMAL).

C. FLIGHT AND FIGHT

1. Agonistic Behaviour.—Agonistic behaviour includes flight, threat, aggression, and fighting. Aggression may be defined as the act of initiating and sustaining an attack. Fighting results from an attack and may be defensive or aggressive in character. Flight involves the avoidance of an attack by running away. Threat is generally a ritualized display involving mixed elements of aggression and flight.

Aggression can be elicited by a variety of stimuli. In some cases the stimulus releasing an attack is quite specific. A red breast induces an attack response by male chaffinches, and similarly a red belly induces attack by male stickleback fishes. Aggression can be enhanced by learning. A mouse may be trained to fight in a specific situation if it is always allowed to win; conversely, it may be trained to avoid or flee if it always loses in a staged encounter. Aggressive behaviour, with a neurohormonal basis, is ultimately determined by heredity. Man has taken advantage of certain hereditary tendencies to fighting in fish, fowl, and dogs, selecting them for his own purposes.

The control of agonistic behaviour is reflected in a variety of behavioural mechanisms. Many animals defend an area or territory around a set of vital resources. In some cases a territory may involve only the nest and a feeding area, but in all cases the living space is divided for best utilization of available resources.

Agonistic behaviour may be divided into two broad categories: interspecific and intraspecific. These categories reflect entirely different selective pressures. In interspecific relations of a predator-prey or competitive nature, selection often favours mechanisms of communication entirely different from those it favours in intraspecific relations. Thus, an herbivore such as the European rabbit has evolved definite flight or freezing patterns when it perceives a sudden stimulus contrast or the odour of a predator. On the other hand, the rabbit is highly territorial and during the breeding season the males fight vigorously with one another over territories containing females in reproductive condition. Very definite communicatory mechanisms are selected to promote intraspecific attack, threat, and submissive behaviours.

Most aggressive displays are ritualizations of basic behaviour patterns that originally reflected ambivalence. When an animal is aroused to fight it generally passes through a preliminary phase during which it has a simultaneous tendency to attack and to flee. It may then show intentions to approach or to avoid, or it may alternate between rushing and withdrawing. Generally, the autonomic nervous system is activated, hormone levels and blood distribution are altered, and hair is raised in a definite pattern. These concomitants of agonistic arousal have provided the substrate upon which selection has acted to produce ritualized threat displays. Such displays frequently suffice to warn away an intruder without the necessity of energy expenditure in an actual fight.

Selection has also favoured the evolution of ritualized combat, which involves a test of strength rather than a fight to the death. Deer mice generally fight with their bellies pressed together; the animals roll about on the ground but do not bite. Norway rats and certain mice exhibit a preliminary fighting phase involving a side display and pushing or upright postures and striking with their forepaws before actually chasing and biting. Deer, cattle, and antelope have antlers or horns that are employed in intraspecific fighting and to a much lesser extent in interspecific defense against predators. The fighting technique in hoofed mammals has involved selection for both ritualized contests and defensive patterns to avoid serious wounding.

Finally, selection has favoured the evolution of submissive displays to inhibit attack by members of the same species (conspecifics). An animal may flee from an attacking conspecific, as is the

case in many birds. In the much studied peck-order hierarchy of chickens, once the degrees of dominance are established, relations among members of the flock are relatively stable and aggression is reduced. In species possessing death-dealing structures such as fangs and claws, bodily harm to conspecifics can only be avoided if a definite submissive posture is evolved that inhibits further attack. This is especially true in species that live in a semi-permanent or permanent social grouping. Konrad Lorenz pointed out the efficiency of such a mechanism in dogs and wolves. When a defeated animal rolls on its back, exposing its vulnerable throat and belly, the posture inhibits further attack by a dominant (*see* also DOG: *Behaviour*). The point is well made that a weapon evolves together with a defensive system. If aggression is allowed unlimited expression, the survival of a species is placed in jeopardy.

2. Value of Aggression.—Aggressive behaviour is not pathological. A species is always in a dynamic state with its environment and the extent to which any agonistic behaviour is displayed is a function of the long-term needs of the species population. Aggression permits the spacing of a population and the establishment of hierarchical relationships. Seasonal fluctuations in aggressive behaviour correlated with breeding is one well-known example of the adaptive nature of aggression.

Aggressive behaviour displayed by man has its physiological and economic bases; however, mankind has invented a new level of aggressive expression termed warfare. War is possible only when a social system is developed enough to support economically the needs of a group that does not contribute to the primary production

of food and raw material. This nonproductive unit can then be geared to perform actions of offense and defense. (Only in the societies of slave-making ants is there an analogous phenomenon of warrior castes supported by a social mass of worker ants in a home colony.)

As technology advances, so also, unfortunately, does it produce tools of greater destruction, operable at distances more and more removed from their effects. Man loses the passion of immediacy, which can move him to violence or to mercy, depending on his victims' responses. He becomes a remote killer, deaf and blind to the mercy-releasing attitudes of his victims. With calculation, unconstrained by the results of his action, he can wreak incredible destruction, of a magnitude beyond the reach of any other animal. This stands in marked contrast to the personal involvement of early man in warfare or the aggressive interactions of other animals. His only hope is in cultural control of aggression, which his expanding technology has not given him time historically to develop. Perhaps the development of "ultimate weapons" by man will force him to adopt "ultimate peace" as the only cultural alternative to his own imminent extinction.

D. Invertebrate Societies

1. Simple Groups.—The simplest form of invertebrate social organization results from an attraction among the members of the group but it lacks any cohesion or coordination of movement. Cockroaches, attracted by the odours of other roaches, regardless of sex or age class, form compact groups in cracks. Such a grouping has been termed an assembly. Assemblies may be seasonal and include such social phenomena as swarming, sleeping, and hibernating groups.

Simple coordinated social groups are those in which the members regulate their behaviour with respect to one another. These include groups arising from reproduction and groups requiring some form of coordination, as among migratory insects that move *en masse* in a directed fashion. Insects that habitually sing as a chorus are able to synchronize their output and form a singing male group with the males spaced out in a predictable fashion.

Pair groups and family groups represent either temporary or long-term social organizations, the primary motivations being sexual drive and solicitation for young.

2. Insect Colonies.—Complex coordinated social groupings exhibit some division of labour outside the reproductive processes. Included under this criterion are such activities as group nest-building, group food storage, and group defense of an area. Such complex integration of activities has reached its culmination in the social insects, especially Isoptera (termites) and Hymenoptera (ants, bees, and wasps).

All the complex societies found in the Isoptera and Hymenoptera are derivations of a family group. Such societies evolved by a series of steps because of the selective advantage accruing from increased parental care.

In the higher termites, the ants and bees, complex societies have evolved independently that show remarkable similarities. Neuter castes have evolved and thus the reproductive success of the founding female (or, in the case of termites, the founding pair) is a function of the success of the whole colony as an integrated unit. This leads to the sometimes held concept of the colony as a supraorganism (see *Extensions and Analogies*, below). A termite, bee, or ant colony is analogous in a functional sense to an organism. Its reproductive success is a function of the total integration of the activities of descendants from a single genetic endowment. *See* SOCIAL INSECTS.

E. Vertebrate Societies

Vertebrate societies, except for man, have never achieved the degree of interdependence found in insect societies. This is primarily because each member of a vertebrate society is a potential reproductive. Neuter castes have not evolved; as a result, vertebrate societies do not approximate the level of a supraorganism but rather remain composed of equipotential individuals.

1. Fishes.—Several social phenomena are exhibited by the teleost or bony fishes including the ability to hold territories and

form dominance hierarchies, family groups, and schools. Many species of fishes form seasonal or permanent groups called schools, which exhibit simple coordination and some cohesion. If a schooling fish is isolated, it will exhibit a rapid series of movements about its living space that increase the probability of its locating other individuals. A fish employs visual, chemotactic, and vibrational cues to locate a school and if isolated will readily join any group passing near it. Many fishes, however, respond selectively when offered a choice between a school of its own species or a school of a different species. Aggressive behaviour is reduced in any school member, but in seasonally social fish the onset of the breeding season results in the breakup of the group and the establishment of individual territories.

Schooling fishes regulate their behaviour with respect to one another so that during linear or turning movements a definite synchrony is maintained, a manifestation of social facilitation. There seems to be a distinct survival advantage provided by schooling, since it evolved independently many times within the teleosts. Certainly there is a mechanical advantage inherent in swimming in a school. The fishes forming the leading edge of the school expend the greatest energy in overcoming the displacement drag of the water; following fishes have a considerably reduced displacement problem. A large school also may locate a food source more easily than a single fish; if one part of a school finds food, the school tends to turn in on the source. Predatory fishes often hunt in schools and encircle schools of the prey fishes. In addition to these selective advantages for schooling one primary advantage stands out: the school is a protective device. A school of fishes, when attacked, responds in a manner that promotes survival; the response corresponds to the adaptive type of the fish. Pelagic fishes, which wander over the open ocean, have several responses to predators including streaming to and fro, which distracts the predator, leaping into the air as a group, forming a dead space around the predator by avoiding it, and inducing avoidance through social facilitation in peripheral school members. Semi-pelagic schooling fishes are generally active in the vicinity of reefs and when attacked scatter as a group into the protection of offshore rocks. Reef fishes generally have special individual hiding places to which they flee individually when the school is attacked. Schooling fishes that are bottom feeders disperse but remain close to the bottom when attacked.

The teleosts have a range of reproductive adaptations with parallel and convergent evolutionary trends. Although many species lay vast quantities of eggs that are fertilized externally, there are definite trends toward laying a smaller number of yolky eggs that require greater parental care. The evolution of internal fertilization with the ejection of fertilized eggs by the female is a step toward the evolution of live bearing (viviparity), which results in the production of fully developed young with greater chance of survival.

Parental care, occurring in the majority of bony fishes, involves constructing a nest (cavity, bubble raft, water weed), guarding the eggs, or carrying the eggs or young in the mouth. The role of parental care may fall to either parent or to both; in general the bony fishes are characterized by father families, in which the male constructs a nest and subsequently defends the egg clutch within it.

The parental care system is adaptive. Darters of the genera *Etheostoma* and *Percina* display two levels of parental care with their adaptive correlates. *Percina caprodes* spawn on the gravel bottoms of small streams. The sexes do not differ conspicuously at the time of reproduction and the male does not defend a definite territory. A male will pair with a female and defend her, but only during the actual course of spawning. The eggs are laid in the gravel in small groups of 3 to 15. A female may spawn with several different males until as many as 2,000 small eggs have been laid. There is no parental care. In contrast, the sexes of *Etheostoma maculatum* show conspicuous differences, the male being brightly coloured and larger than the female. He actively defends a small territory that includes the potential site of egg deposition. The female remains paired with the male and lays eggs singly until about 400 have been deposited. The eggs are large and yolky and the small clutch is defended, cleaned, and fanned by the male. This comparison indicates several important generalizations. Increasing parental care is accompanied by a decrease in egg production. Division of labour in parental care involving defense of a territory is generally accompanied by a strong sexual dimorphism, with the male becoming brightly coloured and developing conspicuous accessory structures advertising his maleness.

Similar evolutionary trends have been described within the family Cichlidae. The more primitive genera exhibit little dimorphism, lay large numbers of eggs, and lay the eggs on the bottom. The pair bond is persistent and the pair cooperatively tend and guard the eggs. From such a parental family several genera have evolved that mouth brood. Mouth brooding involves the uptake of the eggs by one parent into its mouth immediately after spawning. With the evolution of mouth brooding there has been a concomitant increase in egg size and decrease in the total number of eggs laid. Either the male or the female is the mouth brooder, depending on the species; with this division of labour selection has favoured sexual difference in coloration and body size.

In summary, teleost fish exhibit schooling and to some extent territorial and parental care behaviours. The complexity of their social organizations does not exceed that found in the parental family and even with the complex forms of parental care there seems to be no permanent cohesion of the family group. (*See* also FISH.)

2. Amphibians and Reptiles.—Among amphibians complex parental-egg interrelationships may exist, but no special interdependent social unit exists beyond the level of parental care. However, amphibians do exhibit special forms of sociality termed breeding assemblies. These involve homing after a dispersal phase to specific breeding areas such as ponds or streams, participation in choruses by male frogs, and inclusion in breeding swarms of mixed sexes as typified by some species of newts.

Eggs are guarded by males of the salamander genera *Cryptobranchus* and *Hynobius*. The female tree salamander (*Aneides lugubris*) guards her clutch also and several generations may jointly occupy the same cavity in a rotten log. In the midwife toad (*Alytes obstetricans*) the male carries the eggs wrapped about his body. The female Surinam toad (*Pipa*) transports her eggs in special skin pockets on her back. The eggs are encapsulated at the time of spawning after they have been fertilized and pushed into her vascular skin by the male. The male of a Chilean frog, *Rhinoderma darwini*, takes the newly laid clutch into his mouth and forces the eggs into his vocal sacs. The eggs are transported in this moist environment until the time of hatching. Viviparity has seldom evolved in the amphibia, but the salamander *Salamandra maculata* and the frog *Nectophrynoides vivipera* are notable exceptions that bear the young alive. (*See* also AMPHIBIA.)

In general, reptiles are characterized by a lack of complex social organizations. Territorial defense by males is common in the day-active lizards. In species such as *Sceloporus occidentalis*, territorial display and mating rituals are highly developed. Parental care, aside from nest building, is sporadic and extends little beyond guarding the nest. Special forms of social behaviour include mass hibernation in traditional dens by many species of temperate zone snakes. In addition, communal nesting sites are employed by the European water snake (*Natrix natrix*) and some geckoes. Reproduction is completely by internal fertilization, with definite courtship ceremonies preceding copulation. Egg laying is the primitive mode of reproduction, but many species have evolved ovoviviparity, in which the eggs develop within the female until the moment of hatching. A few species of reptiles are truly viviparous and nourish their young by means of a placenta. These include the night lizard (*Xantusia vigilis*) and several species of skinks. In *Xantusia* the female has been observed to break the membranes and pull at the emerging young.

3. Birds.—The social life of birds has been an intensive area of investigation for decades. Conspicuous social phenomena include flocking, pair bonding, complex parental care, territorial defense, colonial nesting, and communal nesting.

Flocking behaviour results from response mechanisms that promote group synchronization and integration. Call notes promote contact while in flight or when dispersed and feeding in dense

vegetation. Social facilitation, or the readiness to duplicate the activities of other individuals, such as straight flight, turning flight, landing, or feeding, is essential in maintaining group synchrony. At the same time, birds very often exhibit mechanisms that promote dispersion. These include such behaviour patterns as individual distance, which may vary according to whether the birds have just arrived on a perch (arrival distance), become settled (settled distance), or recently flown off (departure distance). Individual distance results in part from a tendency to approach or to flee from an approaching conspecific.

Many bird species form flocks outside the breeding season but maintain territories during the rearing phase of the life cycle. Very often the form of the flock reflects the type of social organization at the time of reproduction. Among the African finches, *Euplectes afra* is characterized by a strong territorial defense during the breeding season, whereas *Quelea quelea* breeds in dense colonies in which only the nest entrance itself is defended against conspecifics. Outside the breeding season *Q. quelea* forms dense, synchronized flocks, whereas *E. afra* flies in loose flocks.

Colonial nesting is a common phenomenon among birds. Pairs of birds build separate nests that they defend against conspecifics. All the nests are located close together in some restricted area. Colonial nesting is common among seabirds that occupy a small island or rock cliff for nesting year after year. Communal nesting occurs when two or more females lay eggs in the same nest and share the incubation duties.

The use of one nest by several females has evolved convergently in several families. In the family Cuculidae, which is characterized by the nest-parasitic cuckoo, the subfamily Crotophaginae portrays a series of forms culminating in the communal nesting anis. All crotophagines live in colonies of about 12 individuals. The colony members defend a group territory that includes feeding, nesting, and roosting areas. The primitive species of the Crotophaginae, *Guira guira*, forms pair bonds but the nest defense is weak. This behaviour may have been the prelude to communal nesting. The genus *Crotophaga* is characterized by weak pair bonding and polygamy. The females do not defend their nests against one another, and in *C. ani* several females deposit eggs in the same nest. Colonial nesting does not lead to communal nesting in other bird species. It would seem that communal nesting is facilitated by a breakdown in pair bonding. Factors contributing to loose pair bonding may include physiological changes in the female such as spontaneous ovulation, which reduces the necessity for sustained or prolonged courtship. On the other hand, communal nesting cannot occur unless the species is already a colonial nester. A factor that contributes to colonial nesting is the absence or shortage of available nesting sites. Seabirds are very often colonial nesters on islands or cliffs, but a strong pair bonding prevents communal nesting. In the case of Crotophaginae the colonial nesting habit was probably reinforced in the savannah habitat, the centre of origin for the subfamily. Widely spaced groves of trees favoured colonial life, but the loss of pair bonding by the hypothesized physiological changes within the female promoted communality.

All birds are oviparous and exhibit complex forms of parental care. Parental care includes nest building, incubation, guarding the nest and young, and feeding the young. One or both parents may be involved in the rearing process.

Primitively, birds laid large eggs with copious food reserves. The young were precocial when hatched and needed no parental feeding. The large egg required a long incubation period with a long attentive period by the adult. Advanced birds have departed from the primitive pattern in several ways. The perching birds (*Passeriformes*) are generally small and as a result lay small eggs with a small amount of nutritive yolk. The young are more dependent when they hatch and must be provided with food.

The division of labour between the sexes in parental care runs the gamut from total female care to total male care. In the ostrichlike birds (ostrich, emu, etc.) the male assumes most parental care duties while in most other birds the common trend is for the female to assume the major role in parental care in varying degrees among the different families.

4. Mammals.—The defining feature of mammals is the presence of female mammary glands that produce milk. For this reason parental care of a mother-family type is universal. The simplest set of social relations involves a brief pairing by the male and female, separation of the male and female, and, at birth, the formation of a female-young social unit. Dispersal of the young at maturity coincides with the breakup of the family group. In contrast to birds, mammals very rarely display pair bonding or the inclusion of the male in the role of parental care; such behaviour has evolved only among some primates and carnivores.

Outside the social units resulting from reproduction, mammals exhibit the following social structures: colonies of individuals typified by ground squirrels, communal roosts and hibernating assemblies of bats, herds of grazing hoofed mammals, schools of cetaceans, and hunting packs of certain carnivores. The phenomena of territoriality, dominance hierarchy formation, individual distance, and social facilitation are demonstrable in many mammalian groups.

LOUIS RENAULT FROM PHOTO RESEARCHERS

A COLONY OF CORMORANTS CROWD THE ISLAND OF SAN LORENZO, OFF PERU; THESE BIRDS PAIR AND THEN DEFEND THEIR NESTING TERRITORY

Insectivores.—The order Insectivora includes species of shrews, the males of which exhibit a dispersed spatial distribution except during temporary pair formation, the female and the litter constituting the only social groupings. An exception to this general rule is the least shrew, which apparently does form small family groups consisting of a male, female, and the young. Some insectivores, such as the solenodon or the striped tenrec, may form family groups similar to that described for the least shrew. In general these small mammals do not form complex cohesive societies. Pair bonding is limited and adult male antagonism coupled with the antagonism of the female at parturition prevents stable group formation.

Rodents.—Rodents exhibit a wide variety of social organizations. The European hamster is typically an asocial mammal. The adults defend their individual burrows against intruding conspecifics and the only stable social grouping is the female with her litter. Pairing is very brief, although the male may indulge in a prolonged period of courtship in order to gain entry into the burrow of the female. The male employs chemical communication by marking objects with a flank gland secretion in the territory of the female.

The Norway rat is a more tolerant species. Adults may den alone at low population densities but they are able to form family bands that utilize a common foraging area and burrow system. Strange rats are attacked when they wander into the group territory. Special communicatory mechanisms have evolved to promote contact familiarity including a ritualized crawling over and crawling under behaviour shown by rats belonging to the same family group.

The prairie dog is a highly social species that lives in colonies, each composed of subgroups termed coteries, which include an adult male, several adult females, and their young. Coterie members defend a group territory against strangers. A variety of contact postures promote and reinforce recognition among coterie members. The beaver is also highly social, and lives in a family group composed of an adult male and female with the current litter and the young of the previous year. The beaver family utilizes a communal lodge and foraging area. Their group activities result in complex artifacts such as dams, food caches, and lodges. Apparently each beaver family is a closed social unit, and intruding conspecifics are repulsed.

Ungulates.—As in all mammals, the basic social unit is the female and her infant. Most young ungulates are able to follow the female shortly after birth. Within a few hours the female recognizes her young, and in the course of a few days the young animal knows its mother. Some ungulate females, such as the moose, are asocial during the rearing phase, but many, such as the red deer, exhibit strong herding tendencies.

In many ungulate species, including the red deer and the bighorn sheep, the adult males form loose herds separate from the female herds. Other species, such as the bison, may tend to form unisexual subgroups but may also form a large herd of mixed sexes. The size of the herd is related to the habitat; *e.g.*, dense forests or mountainous areas prevent the formation of large groups. The largest herds are formed by those ungulate species adapted to an open savannah or grassland habitat.

During the breeding season the males tend to become antagonistic toward one another. Many ungulate species exhibit a pronounced sexual dimorphism, with the males bearing conspicuous antlers or horns, which are used to intimidate or to fight. The male fights lead to the establishment of dominance or to the defeat of rivals, thus conferring on the dominant a mating priority.

The type of mating system in part depends on the size of the female group. Solitary ungulates form brief pair associations; however, species that typically form large herds of females and their offspring usually exhibit generalized mating systems. In species like the red deer, typified by extreme male-male antagonism during the rut, one male attaches himself to a female group and establishes a harem. If the males are more tolerant, as among bison, and are loosely attached to a female herd, the males will establish a dominance hierarchy with the dominant male accomplishing most of the breeding.

A mating system found in the Uganda kob involves dominance and the defense of a territory. The adult males have a traditional breeding ground where they establish and maintain small territories. The receptive females individually approach this breeding ground and join a male, generally one whose territory is centrally placed.

Ungulates and rodents have evolved social systems significantly more complex than those typified by most of the smaller insectivores. Living in herds, colonies, or communal family bands correlates with a shift from high energy diets including meat, nuts, and seeds to low-energy diets composed mainly of grasses. The shift to grass as the main foodstuff has been accompanied by major changes in dental patterns and in the digestive tract. The eating of grass is generally accompanied by a loss of the food-caching instinct and the adoption of behaviour patterns ensuring survival in an open habitat. Colonial life in the prairie dog and herd life in the bison and other plains-dwelling ungulates is an overall adaptation to promote warning and escape from predators. Herding or colonial life is possible in the grass eaters because the environment can support many more cellulose feeders per acre than it can animals utilizing high energy food sources such as seeds or, in the case of carnivores, other animals.

Carnivores.—Terrestrial carnivores are typified by a high potential for social interaction. As young animals, carnivores engage in complex play activities involving elements of sexual, prey-catching, and agonistic behaviour. As adults, however, many carnivores are solitary. This is especially true for those species that hunt by stealth, such as the cats. On the other hand, canids such as wild dogs, wolves, and coyotes, which must hunt by cooperatively running down game in a semi-open habitat, typically live in social groupings. It is noteworthy that the cheetah, unlike other cats, is adapted for hunting in a typically canid fashion and has evolved the tendency to hunt in small family groups.

All terrestrial carnivores produce helpless (altricial) young. They are reared in a protected spot and are generally immobile during their first few weeks of life. Group-hunting canids exhibit the phenomenon of provisioning whereby the male aids the female in bringing food to the den site for the young. Provisioning occurs in species that exhibit pair bonding or that live in small groups. Group life for a carnivore is possible only if the species is mobile enough to forage over a large area. The habit of food provisioning acquires a distinct survival advantage for the species, especially when the pregnant female is confined while giving birth.

Some examples for the major social systems found in the terrestrial carnivores may be listed as follows: species showing pair bonding with provisioning at parturition and the formation of small hunting groups (wolf, coyote, red fox); species utilizing a common nesting site for several generations (European badger); species living in loose hunting groups with little pair bonding (lion); species generally solitary except for a brief pairing period (bears, most cats, and most weasels); species forming a foraging unit of females with their young (coatimundi).

The aquatic carnivores include otters and pinnipeds (seals, sea lions, and walruses). The pinnipeds forage at sea but return to land or ice to breed, to molt, and to rear their young. Dense colonies may be formed during the breeding season, especially in species that are migratory and have a traditional, insular breeding ground. Two general types of social organization during the breeding season may be discerned. The first system is characterized by pronounced male-male antagonism and the formation of harems. Such polygynous breeding systems are typical of the elephant seal, fur seal, and gray seal. On the other hand, seals of the family Phocidae, including the common harbor seal, do not form harems but rather exhibit a promiscuous breeding system. Species having a harem system during the breeding season also exhibit a pronounced sexual dimorphism; the males may be two to three times as large as the females.

F. Primate Societies

Primates have exhibited several independent adaptive radiations during their evolutionary history. These include the evolution of the lemurs on Madagascar, the radiation of the platyrrhine mon-

keys in South America, the radiation of the catarrhine monkeys in the Old World, and the evolution of the anthropoid apes, including man.

1. Lemurs.—The lemurs exhibit a diversity in social structure that parallels certain adaptive trends already discussed. The mouse lemurs of the subfamily *Cheirogalinae* are nocturnal forest dwellers adapted to feeding on insects, small vertebrates, and some vegetable matter. These species have two to three altricial young and typically do not form pair bonds or permanent social groupings. In this way they exhibit tendencies parallel to those found in the insectivores. The larger lemurs of the family *Indridae* are vegetarians that produce one young having a prolonged period of development and maturation. Some indrids are diurnal and others nocturnal or crepuscular (twilight-active). All species appear to live in family groups. The true lemurs (family *Lemuridae*) are vegetarian and crepuscular. As with the indrids, they produce one semi-precocial young with a prolonged maturation period. They typically live in troops of adults of mixed sexes.

2. Higher Primates.—The higher primates, including the larger monkeys and the apes, are all characterized by a rich social life. The infants undergo a relatively extended period of maturation accompanied by a highly social interaction with their peers and with adults of both sexes; however, there is still much diversity in the exact form of the social organization. Communication mechanisms include visual and auditory signal systems. The higher primate facial expressions and vocalizations permit a graded series of expressions with a concomitant complexity of information transfer.

The social composition of the different groups varies. Some marmosets, the lar gibbon, and the night monkey live in family groups consisting of one adult pair and their juvenile or infant offspring. Species such as the spider monkey and the sacred baboon may live in loose troops composed of more cohesive subgroups. The subgroups are usually (1) females with their young accompanied by one adult male; (2) groups of adolescents of both sexes; or (3) all male subgroups. Species such as the howler monkey, the chacma baboon, and the rhesus monkey live in large troops of adults, juveniles, and infants. Some tendency toward the formation of unisexual or age-specific subgroups may be shown, but these species tend to be quite cohesive in their movements.

All primates have a predictable home range where they forage and sleep. The howler monkey, gibbon, and rhesus monkey tend to defend these areas against intruders. The chacma baboon, however, exhibits no overt agonistic defense and yet maintains a core area in its home range that is relatively free from invading conspecifics. The chimpanzee appears to exhibit no defense of a specific area but wanders freely in its home range, mingling with other chimpanzees and then separating. The cohesion of groups may be pronounced as in the case of the howler monkey, gorilla, and baboon; on the other hand, the chimpanzee exhibits little cohesion and groups are constantly forming and splitting. As a consequence, the chimpanzee troop is very permeable to outsiders, but the howler monkey and baboon societies remain essentially closed to infiltrators.

In the gorilla troop the oldest adult male initiates movement and controls the duration of rest periods. To some extent the dominant adult male baboons initiate and direct movements, although a baboon troop on the move exhibits a pattern that places the dominant males in the centre of the group. The actual leading edge of the troop is composed of the young males, who, consequently, are the first to contact a dangerous situation and give warning. Thus the function of vigilance and composition of the vanguard falls to the younger males, although the dominant males control the general direction and rate of movement.

Assertion of dominance may be weak and scarcely noticeable in species such as the Indian langur; on the other hand, dominance may be overly expressed in the rhesus or baboon troops. Dominance results from a long process of learning. Adult males are dominant over females and younger males; among the adult males as well as the adult females a definite hierarchy exists. A dominant animal has freedom of access to food and mates, thus a definite advantage exists for those attaining a superior social status. Reproductive control is achieved through dominance. In howler monkey, baboon, and macaque troops an estrous female typically consorts with several males, although the dominant frequently has access to a female at the height of her estrus period.

Primates demonstrate several trends in the evolution of sociality. The higher primates have departed from the patterns of nocturnality, omnivorous diet, and the production of rapidly maturing altricial young. Instead, one finds in the higher primates diurnality, a vegetarian diet, and the production of a single young capable of clinging to the mother but undergoing a prolonged period of maturation. The long period of maturation allows for an extended period of socialization. Young primates appear to be dependent on a rich social environment for the normal development of their patterns of behaviour. Experiments involving isolation of young rhesus monkeys demonstrated the complete lack of normal sexual behaviour in monkeys reared alone. Daily play with other juveniles compensates, in large part, for the effects of rearing in the absence of a mother (*see* PRIMATES: *Socialization*).

In spite of their social life and dependency on a rich social environment, primates do not exhibit group hunting activities or provisioning for the female. Food sharing is almost unknown except between the female and her infant. Coordinated activities are demonstrated by male baboon groups during defense against predators, or by male howler monkeys in their vocalization ceremony used to establish the bounds of their territory against neighbouring troops. Selective advantages promoting group life thus appear to be related primarily to defense against predators, to the maintenance of a group territory, or to the acquisition and maintenance of access to estrous females.

Selective pressures promoting social organization vary depending on the overall adaptive syndrome of the species, and variations are quite common. The marmosets exhibit pairing tendencies and the male carries the young thus participating directly in parental care. This adaptation may have resulted from the peculiar energy demands on a very small species faced with the problem of continually transporting the young during the rearing phase. The energy requirements of the lactating female may be such that to be relieved of the burden of transporting the young is of extreme selective advantage. The obvious selective advantage promoting group cohesion in the baboon and macaque is the transition from an arboreal to a terrestrial life with the attendant dangers of increased predation pressure. Group defense of the troop by the adult males confers a definite survival advantage.

3. Men.—Man's early pre-australopithecine ancestors were probably organized into social bands similar to that of the baboon. At this time man was an herbivore-omnivore foraging on the ground. At the australopithecine stage man had transformed his economy and become a hunter. (The contemporary mammalian economy that most nearly approximates australopithecine man's economy is that of the pack-hunting canids. The canids typically show group hunting and provisioning of the female. For similar economic reasons australopithecine man must have begun to develop a similar type of social system.) Somewhere between the level of australopithecine man and pithecanthropus man there developed a tendency to establish permanent family subgroups within a hunting group and to form cultural control systems of kinship, taboo, and religious symbolism.

Primate species such as the Japanese macaque may exhibit learned traditions of food selection that are passed on from generation to generation in the same manner that cultural traditions are passed on in human societies. While man's cultural attributes and use of tools has its roots in the behaviour patterns of his subhuman predecessors, he has ordered them and recorded them as no other species has.

Man has achieved a fantastic degree of complexity in his modern societies. His division of labour and interdependence have proceeded by two methods: (1) the creation of a fixed caste system exemplified by the guilds of renaissance Europe or the social structure of India in the last century; (2) the erection of a series of economic divisions with a free choice of occupancy. When Western society opted for a social philosophy based on equal opportunity for all mankind, it effectively banished the notion of fixed castes

and permitted a great mobility among the members of its society. Stability in Western society was conferred by the great complexity and division of labour demanded by technological advances. Such complexity provides an internal compensation analogous to compensation mechanisms found in the physiology of whole animal organ systems.

Yet even with such interdependence and specialization in modern society, persons remain independent units of reproduction and enjoy a social mobility conducive to individual development and freedom.

IV. Extensions and Analogies

Great care must be exercised in forming judgments about probable social behaviour in untested situations and especially about inner social feelings of animals under any conditions. It is unsafe to assume, without direct information, that one order of birds will show social patterns closely resembling those of some species belonging to a different order. It is still more hazardous to try to estimate the degree and kind of sociality across wider taxonomic gaps. For example, pending direct inquiry, it is unsafe to predict that individual-to-individual social hierarchies exist among sharks from the fact that such social rank-orders exist among many species of bony fishes.

Still greater caution must be exercised, again pending direct information on the precise point at issue, before making extrapolations between human sociality and the social life of other species. Men may and do disregard or compensate for inconveniences based on position in the social "peck-order," but we cannot judge therefrom that other animals do likewise. Despite the need for great restraint in such matters, stimulating cross comparisons can be made that help to integrate animal sociology into a unified whole despite the marked differences between the social relations of man and those of other animals.

1. Organism and Supraorganism.—The analogy between the biological processes within the organism and the sociological processes within society long ago attracted attention. Thomas Hobbes' *Leviathan* and the less cumbersome comparisons of Herbert Spencer in his discussion of the analogies between the organism and society are matters of historic interest only, but they did more or less vaguely foreshadow the modern realization, particularly by biologists, that similarities exist between individual organisms and organized social groups. Since even ecological communities, as well as more closely knit societies, behave as more or less integrated entities, they are often regarded by biologists as representing a set of emergent levels concisely designated as supraorganisms.

Biologists do not stress the resemblances between societies and a closely coordinated organism such as an insect or a man. They do see a few resemblances between the social supraorganism and simpler invertebrates. Sponges, for example, often have one part of the individual colony working in direct opposition to another when the cooperation of both is needed for efficient operation of the whole. Starfish, in righting themselves, and even in walking across a smooth surface, often tear off some of their tube feet that were working in opposition to the movement of the whole.

Society, human society as well as an insect society based primarily on inherited behaviour patterns, shows many pertinent comparisons with these more poorly integrated organisms, and yet primitive organisms and primitive or advanced societies are somewhat integrated wholes. The chief value inherent in the application of the supraorganismic concept to animal communities or societies lies in the suggestion of analogies. Similar mechanisms of integration that are in many cases not homologous become apparent through comparisons made within such a unified outlook.

Insects and mammals stand near the apex of their respective evolutionary branches of the animal kingdom. The similarities between the social life developed in each class are mainly matters of convergence and analogy. To the extent that the sociality of each develops from the cooperative tendencies of their common ancestors, their sociality is vaguely homologous. In many ways this is not a minor point. Even the sociality of man in all probability developed from basic drives that pervade all higher vertebrates. While such drive-systems in man are emancipated in part from their original stimulus fields, some continuity still remains.

2. Subsocial and Social Levels.—For general and comparative sociology, the chief interest is not between extrapolations from the organismic to the supraorganismic level in organization—from the biological to the social, so to speak—but rather in the permissible extrapolations from the subsocial to the truly social levels and in the opposite direction as well. Here again arises the problem as to where truly social life begins.

A part of the difficulty involved in answering this question may be avoided if it is recalled that many different levels of social organization exist and that these usually overlap. Among all the groups that the biologist regards as somewhat more social than is usually implied by more vague ecological relationships, the following may be recognized: (1) Those that show their social habit merely through the toleration of the close proximity of other similar animals in the same restricted space; these may exist without any positive mutual attraction and represent the toleration level of sociality. (2) Those groups that react more or less definitely as units—the group-integration level. (3) Those that show physiological division of labour. (4) Those that show morphologically distinct castes, each associated with some phase of the division of labour (the highest insect level). (5) Those that are organized to a large part by tradition and by symbolic communication and that frequently react to abstractions (the human level).

In presenting this abbreviated list of recognized social levels, there is no intention of assuming that the more complex types of social life evolved through the less complex ones. Such may or may not have been the course of social evolution. The insects do not stand in the direct line of man's ancestry. Their state of social development represents an insect evolution of sociality, not a stage toward that found in man.

Animals on the higher planes of sociality continue to show certain of the group attributes characteristic of the lower levels. Group survival values have been demonstrated throughout the whole series and apparently extend to the threshold of primitive life. Extrapolations forward from the lower to higher social levels can be made with more confidence than those in the opposite direction. It can be predicted, from studying the social survival values of primitive organisms, that, other conditions being equal, groups of more complex animals will have certain cumulative and emergent survival values as groups. It is much more hazardous to try to project highly developed human social traits, like social consciousness, back into the less complex social levels reached by other animals.

3. Conclusion.—A survey of animal societies indicates that tendencies toward cooperation and competition coexist as polar opposites within all phyletic levels of interorganismic activity. Which of these two tendencies is the more fundamental? Considering the evidence available, contrary to Herbert Spencer and the conclusions of social Darwinism, the cooperative forces equal the competitive in biological and sociological importance.

A survey of evolutionary trends indicates that organisms, societies, and ecological communities have tended to become more complex, interdependent, and integrated. The greater biological stability imposed by increasingly complex chains of organismic interaction confers tremendous survival value. However, this trend toward greater integration and complexity does not mean the loss of the capacity to express aggression or compete through ritualized aggressive mechanisms. Thus man, when viewed as an animal, must be considered as having both a natural capacity for socialization and at the same time the potential for expressing no inconsiderable amount of aggression. A rational consideration of man's nature should, then, take into account all of man's natural potential rather than seek to deny the multipolar nature of his biological background.

SOCOTRA (SOKOTRA; SUQUTRA), an island in the Indian Ocean, about 150 mi. (240 km.) ENE of Cape Guardafui, Somali Republic. Socotra is a dependency of the Mahri sultanate of Qishn and Socotra which forms the easternmost state of the British Protectorate of South Arabia, previously known as the Aden Protectorate. The island is about 70 mi. (110 km.) long, has an average breadth of more than 20 mi. (30 km.) and an area of about 1,200 sq.mi. (3,100 sq.km.). It is the most easterly of a group, of which Socotra and the islets of Samhah and Darsa (called the Brothers) are on united coral banks 10 to 30 fathoms deep. 'Abd al Kuri, 60 mi. from Socotra, is separated from them by a seavalley of 100 fathoms, and there are also two rocky islets, 13 mi. from 'Abd al Kuri, called Ka'l Fir'awn.

The summits of Socotra, Jabal Haggier (4,656 ft. [1,419 m.]), Samhah (2,440 ft. [744 m.]), and 'Abd al Kuri (1,670 ft [509 m.]) are among those land surfaces which have been longest, if not always, above water. There are wild asses of Nubian origin, humpless cattle, resembling small Alderneys, and sheep apparently of degenerate European type. Of the flora, dragon's blood (*Dracaena*), myrrh, frankincense, and cucumber trees are most famous. The affinities of flora and fauna are not only Asian and Ethiopian, but Mascarene, South African, and Antipodean-American.

History.—The name Socotra, and its Greek and Roman form, Dioscorides, is usually traced back to the Sanskrit Dvipa-Sakhadara, "island abode of bliss." It has been identified with the Egyptian Pa-anch, the Panchaia of Virgil, as well as the Isle of the Blest where Gilgamesh obtained a tree of life. The quest for immortality may have been the motive in the South Arabians' first use of incense and is reflected again in the legend of the phoenix, which has been associated with Socotra, as has that of Castor and Pollux. Dragon's blood is still called *dam al-'akhwein*, "the blood of the two brothers," the dragon and the elephant. Iskuduru, a country conquered by Darius the Great of Persia, may have been Socotra, and it was probably visited, with Punt, by the Egyptians in search of myrrh and frankincense. The *Periplus of the Erythraean Sea* (1st century A.D.) mentions a foreign population of Arabs, Indians, and Greeks and says that Socotra traded with Al Mukha in Yemen and with the Tamil country and Broach in India. The inhabitants of Socotra were for long Christians, probably Monophysites, and in the reign of the Roman emperor Constantius II the ambassador and bishop Theophilus Indus included Socotra in his diocese. Cosmas Indicopleustes (6th century) thought the Ptolemies had placed Greeks there. St. Francis Xavier, visiting Socotra after 1541, believed the inhabitants to be Nestorians. The last recorded traces of Christianity were in the 17th century. The Portuguese occupied Socotra from 1507 to 1511 when it reverted to the Mahri sultan.

In 1834 the British made an agreement for storing coal in Socotra and negotiated for the purchase of the island. A detachment of troops was sent but withdrawn when the sultan firmly refused to sell. In 1838 he proposed to hire the island to the British but the capture of Aden made this unnecessary. In 1876 the sultan agreed not to cede to any other power and by treaties of 1886 and 1888 accepted British protection for the whole sultanate. In 1954 an advisory treaty was signed between the sultan and the British government.

Population, Administration, and Social Conditions.—The population of Socotra is estimated at 12,000, the capital Hadibu (formerly called Tamrida by Europeans) may have a population of about 1,000 out of the 4,000 or 5,000 settled inhabitants of the coastal villages. The pastoral nomads of the interior possibly number rather more. The Socoteris are largely of Mahri origin, but are different in manners from the Mahris of the mainland. The Socoteri language also differs from Mahri, but both belong to the Hadara group, spoken by Veddoid tribes called Ahl al-Hadara, identified with the Hadoram of Genesis.

Socotra is directly ruled by the Mahri sultan. Its status as a possession of that chief is very old The *Periplus* describes it as being subject, by some ancient right, to "the king of the frankincense country," which included the Hadhramaut, the Mahra country, and probably the Qara country (now in Oman), which produced most of the incense.

The sultan's constitutional position in his own country differs greatly from that in his dependency Historically he is not recognized, nor does he claim any right to rule in the former, while in the latter his power is absolute. The Mahri nation which includes the Mahri tribe, is matrilineal and divided into four *'useba* (each consisting of a number of clans), and some independent clans, not all true Mahris. Of these latter the "royal" clan, Bin'Afrar, claims common origin (with the Beni'Afif sultans of Lower Yafa' in the western area of the Protectorate of South Arabia) from the Himyarite god Yafa'. There are two branches of the "royal" clan, the Sa'd bin Towar and the 'Amr bin Towar. The sultan belongs to the former, and recent sultans have preferred to live at Hadibu while the head of the latter represents him on the mainland at Qishn with a cadet of the branch at Sayhut. The Mahri "system of anarchy" depends closely on recognized relationships and functions of the *'useba* with each other and the Bin'Afrar clan. In interclan functions the principal *'useba* is the Bin Sar which includes the Bin 'Ali Muqaddam clan. The *muqaddam* (chief) determines disputes between any two clans and arranges truces. A man declared guilty of murder by the *muqaddam* during a truce should be slain by his clansmen. An appeal lies from the *muqaddam* to the sultan but neither has jurisdiction in internal clan affairs. In external affairs the Bin Boqi bin Ahmed *'useba* is responsible for defense against outside aggression. This

originated with an invasion of Kathiris in the 15th century when the sultan brought in Yafa'i mercenaries to expel them. The Bin Boqi thereafter guaranteed Mahraland against foreign invasion and still receive an annual retainer of 480 thalers. They also receive 120 thalers from the sultan of Muscat for a guarantee of nonaggression.

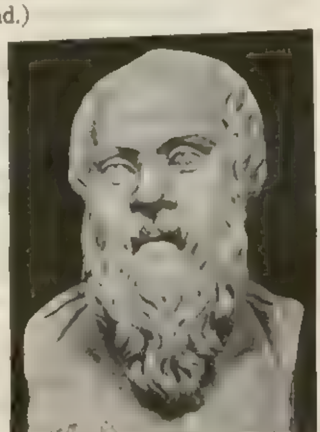
The sultan exercises his direct, but somewhat primitive, rule in Socotra with the aid of a vizier and the headmen of the settlements and pastoral clans. Though the tribesmen in the Mahra country are, like all tribesmen in the Protectorate of South Arabia, entitled to bear arms, those in Socotra apparently never have been, but the sultan has a few armed retainers, mostly of African slave descent, to execute orders. Tribal law applies, but there is a *qadi* (judge) and the *shari'ah* (Islamic law) is sometimes enforced.

The Economy.—About half the settled inhabitants of the coastal villages are fishermen and part-time pearl divers. Others have gardens but few domestic animals. The small foreign community are almost all traders. The pastoral nomads own about 20,000 cattle and more than 1,000 camels. They make the highly valued Socotran ghee, collect dragon's blood, aloe juice, and frankincense, and also civet from trapped animals. They grow a little tobacco, Eleusine millet, and inferior dates. Hadibu is the largest settlement and principal anchorage. No anchorages are safe, however, during the southwest monsoon. Qadhub has a large Royal Air Force airfield established in 1942 for antisubmarine operations. (W. H. Is.)

SOCRATES (*c.* 470 B.C.–399 B.C.), the great Athenian philosopher. Since he was 70 years old when he was put to death in 399 B.C., he must have been born in or about 470, ten years after the Battle of Salamis. His father, Sophroniscus, was a friend of the family of Aristides the Just (the tale that he was a sculptor first appears in the 3rd century B.C. in Timon of Phlius and seems to be only a misinterpretation of a playful remark in Plato). The philosopher's mother, Phaenarete, acted as a "midwife," but no inference as to social status can be founded on this.

The memoir writer Ion of Chios mentioned meeting Socrates at Samos in the company of the philosopher Archelaus, the Athenian pupil of Anaxagoras, presumably during the military operations of 441–440; and the connection between the two men is also asserted by Aristoxenus (*q.v.*), while the doxographical tradition based on Theophrastus calls Socrates the "disciple" of Archelaus. Plato, Xenophon, and Aeschines of Sphettus agree in depicting him as intimate with the leading figures of the Periclean circle (Aspasia, Alcibiades, Axiochus, Callias). Xenophon concurs with Plato in saying that he was well versed in geometry and astronomy, and this representation agrees with the narrative of Plato's *Phaedo* and the Aristophanic burlesque of *The Clouds*. Socrates must already have been a conspicuous figure at Athens when Aristophanes and Ameipsias both made him the subject of their comedies in 423, and since they made a special point of his neediness he had probably suffered recent losses. (The marked poverty of his old age is said in Plato's *Apology* to have been caused by his preoccupation with his mission to mankind.)

Socrates was married, apparently late in life, to Xanthippe, by whom he left three sons, one an infant. Xenophon speaks of her high temper; there is no evidence that she was a "shrew"; the sons, according to Aristotle, proved insignificant.



BY COURTESY OF THE SOPRINTENDENZA ALLE ANTICHITÀ DELLA CAMPANIA, NAPLES

BUST OF SOCRATES

Socrates' record for endurance was distinguished. He served as a hoplite, perhaps at Samos (441–440), and, during the Peloponnesian War, at Potidaea (432–430; where he saved the life of Alcibiades), Delium (424), and Amphipolis (422, unless he went on the expedition of 437–436). In politics he took no part, knowing, as he told his judges, that office would mean compromise with his principles. Once at least, in 406–405, he was a member of the boule (*q.v.*) of 500; and at the trial of the victors of Arginusae, he resisted, at first with the support of his colleagues, afterward alone, the unconstitutional condemnation of the generals by a collective verdict. He showed the same courage in 404, when the oligarchy of the Thirty Tyrants in Athens, wishing to implicate honourable men in their proceedings, instructed him and four others to arrest Leon, one of their victims: Socrates disobeyed, and says, in Plato's *Apology*, that this might have cost him his life but for the counterrevolution of the next year. (For the background to these events *see* GREECE: *History*.)

In 399 Socrates was indicted for "impiety." The author of the proceedings was the influential Anytus, one of the two chiefs of the democrats restored by the counterrevolution of 403; but the nominal prosecutor was the obscure and insignificant Meletus. There were two counts in the accusation, "corruption of the young" and "neglect of the gods whom the city worships and the practice of religious novelties." Socrates, who treated the charge with contempt and made a "defense" which amounts to avowal and justification, was convicted, probably by 280 votes against 220. The prosecutors had asked for the penalty of death; it now rested with the accused to make a counterproposition. A smaller, but substantial, penalty would have been accepted, but Socrates took the high line that he really merited the treatment of an eminent benefactor, maintenance at the public table. He consented only for form's sake to suggest the small fine of one *mina*, raised at the entreaty of his friends to 30.

The claim to be a public benefactor incensed the court, and "death" was voted by an increased majority, a result with which Socrates declared himself well content. As a rule at Athens the condemned man "drank the hemlock" within 24 hours, but in the case of Socrates the fact that no execution could take place during the absence of the sacred ship sent yearly to Delos caused an unexpected delay of a month, during which Socrates remained in prison, receiving his friends daily and conversing with them in his usual manner. An escape was planned by his friend Crito, but Socrates refused to hear of it, on the ground that the verdict, though contrary to fact, was that of a legitimate court, and must therefore be obeyed. The story of his last day, with his drinking of the hemlock, has been perfectly told in the *Phaedo* of Plato, who, though not himself an eyewitness, was in close touch with many of those who were present.

Main Sources of Information.—Socrates wrote nothing; therefore our information about his personality and doctrine has to be sought chiefly in the dialogues of Plato (*q.v.*) and the *Memorabilia* of Xenophon (*q.v.*). Both men were nearly 45 years younger than Socrates, and could therefore speak from firsthand knowledge about only the last 10 or 12 years of his life.

Xenophon, whose relations with Socrates seem not to have been close, has even been suspected of deriving much of his material from Plato's dialogues. His admitted deficiencies in imagination and capacity for thinking do not make him the more faithful exponent of a philosophical genius. We need also to discount Xenophon's apologetic purpose. His most valuable statements are those which appear most at variance with his main thesis that the prosecutors of Socrates were mistaken from their own point of view.

Plato's more vivid picture has been suspected on the ground that Plato used Socrates as a "mouthpiece" for speculations of his own. What this really means is that the "ideal theory" or doctrine of "forms" expounded in the *Phaedo* is held to have been originated by Plato after the death of Socrates. There are serious reasons for denying this assumption though they have not yet convinced all scholars; in any case it is a *petitio principii* to employ it, without investigation, as an argument to discredit Plato's testimony. Xenophon's silence at most only proves that Socrates did not converse on such matters with him.

In some important respects Plato's testimony is confirmed by the remains of Aeschines of Sphettus. *The Clouds* of Aristophanes yields valuable information about Socrates in his middle 40s,

though allowance is made for the work's character as a burlesque. It should be compared carefully with the autobiographical statements put into the mouth of Socrates in the *Phaedo* (*Great Books of the Western World*, vol. 7, pp. 240 ff. [96*a*–100*a*]). These are not "contemporary evidence," but they are clearly meant to express Plato's bona fide belief about his master's intellectual history.

Personal Characteristics.—Though Socrates was a good fighting man, his outward appearance was grotesque. Stout and not tall, with prominent eyes, snub nose, broad nostrils, and wide mouth, he seemed a very Silenus. But, as his friends knew, he was "all glorious within," "the most upright man of that day" (Plato, *The Seventh Letter* [324*e*]). His self-control and powers of endurance were exemplary; "he had so schooled himself to moderation that his scanty means satisfied all his wants."

But Socrates was no self-tormenting ascetic; he "knew both how to want and how to abound," and could be the soul of the merriment at a gay party. He had no sympathy—this was a main point in the *Telauges* of Aeschines—with the slatternliness of his friend Antisthenes or the godly dirtiness affected by "Pythagorists." There was nothing of the complacent self-righteousness of the Pharisee, nor of the angry bitterness of the satirist, in his attitude toward the follies or even the crimes of his fellowmen. It was his deep and lifelong conviction that the improvement not only of himself but of those with whom he might have to do was a task laid upon him "by God"; but the task was not to be executed with a scowling face and an upbraiding voice. Like St. Francis Xavier, he thoroughly understood how important it is to one who would win men's souls to be "good company." Conscious of his own infirmities, he felt a real and profound sympathy for those who had not learned to master their frailties and passions.

Socrates was a true patriot, and his devotion to Athens was made only the more evident by his conviction that he could best prove it by setting his face resolutely against the attractions of specious and popular, but deadly, false theories of public and private morality. When the city brought him to trial and threatened him with death his sense of civic duty forbade him to withdraw into exile before the trial, or to accept the opportunity of escape during his unforeseen imprisonment. It was his very patriotism that made him an unsparing critic of the "democracy," which means, in Friedrich Nietzsche's phrase, "one flock and no shepherd," and so led directly to the accusation that proved fatal to him.

Nothing was more marked in his character than an unusually keen sense of humour, an appreciation of the comic in human nature and conduct that protected him at once against sentimentality and against cynicism. This is what his opponents in Plato call his "irony," and treat as an irritating affectation. "Intellectually the acutest man of his age, he represents himself in all companies as the dullest person present. Morally the purest, he affects to be the slave of passion" (W. H. Thompson, *The Phaedrus of Plato*, 1868). No doubt, in part this irony was "calculated"; it "disarmed ridicule by anticipating it." But its true source is the spontaneous sense of "fun" which makes its possessor the enemy of all pretentiousness, moral or intellectual, in himself and in others. And it is certain that, though the purity of Socrates is beyond question, he really had an ardent and amorous temperament; a fragment of the *Alcibiades* of Aeschines confirms Plato's representation on this point.

Religion.—Socrates was clearly a man of deep piety with the temperament of a mystic. Like other educated men of his age, he regarded mythology, with its foolish or immoral tales about gods, as a mere invention of the poets. But he found it easy to combine his own strong belief in God, the all-wise and all-good ruler of the world, with the view that in practice we could worship God in the way prescribed by "the usage of the city." God's existence is shown, he held, not only by the providential order of nature and the universality of the belief in him but by warnings and revelations given in dreams, signs, oracles. The soul of man partakes of the Divine; the concluding pages of Plato's *Apology* prove that Socrates had a strong belief in the soul's immortality. (Xenophon for apologetic reasons is silent on the point, but has reproduced the argument in the dying speech of his Cyrus in the *Cyropaedia*. Aristophanes, too, makes Socrates combine the parts of "infidel" physicist and hierophant of a mysterious private faith, and in *The Birds* [1553, *seq.*] represents him as presiding at a fraudulent séance.) He was regular, says Xenophon, in prayer and sacrifice, though he held that since only the gods know what is good for us, our prayer should simply be "give me what is good"; we must not dictate the form the blessing should take. It is clear from Plato that Socrates was deeply influenced by Pythagorean and Orphic religious ideas, though he regarded the ordinary Orphic mystery-monger with healthy contempt.

The evidence that Socrates had a markedly "mystical" temperament is abundant. Plato tells of his curious "rapts," in one of which he stood spellbound for 24 hours in the trenches before Potidaea, and there seems to be an allusion to this singularity in *The Clouds* (171, *seq.*).

The accounts of the philosopher's "Divine sign" tell the same story. This, according to Plato, was a "voice" often heard by Socrates from childhood. It forbade him to do things, but never gave positive encouragement. (Xenophon, who makes more of the matter, says, less probably, that it did give positive directions.) Plato treats the "voice" very lightly; by his account, it merely gave prognostications of good or ill luck, and the occasions of its occurrence were often "very trivial." Thus it was neither an "intuitive conscience" nor a symptom of mental disorder, but an "interior audition," a "psychic phenomenon" of a kind not specially uncommon.

Mode of Life.—Socrates' whole time seemed to be spent "out of doors," in the streets, the marketplace, and, more particularly, the *gymnasia*. He cared little for the country and rarely passed the gates. Though he frequented by choice the society of lads of promise, he also talked freely to politicians, poets, artisans about their various callings, their notions of right and wrong, the familiar matters in which they might be expected to take an interest. The object of all this, he says in the *Apology*, was to test the famous Delphic oracle that had pronounced him the wisest of men. It is clear from the *Apology* that the oracle had made this declaration, no doubt because the Delphic authorities knew from the form of the question what answer was desired. The presupposition of the *Apology* is that this happened before Socrates had become conscious of his mission to his fellowmen; even at that early date, it is implied, he had the highest of reputations in circles interested in wisdom. Moreover, the Eleatics from Megara and the young pupils of the Pythagoreans from Thebes and Phlius who were attached to Socrates must have formed their connection with him before the Peloponnesian War.

Acutely sensible of his own ignorance, Socrates set himself to convict "the god" of falsehood. But when experience showed that those who thought themselves wise were unable to give any coherent account of their wisdom, Socrates had to admit that he was wiser than others, just because he alone was aware of his own ignorance. This account is plainly tinged with the usual "irony." Socrates did not take Apollo and his oracle very seriously. But that he was quite serious in believing himself charged with a mission, not from "Apollo" but from God, to preach to his fellowmen the supreme importance of knowledge of what is for the soul's good is proved by his declaration that he was more than ready to face instant death rather than to neglect his commission. The poverty in which this mission had involved him and the austerity of the rule of life which it entailed were notorious.

Summer and winter, Socrates' coat was the same; he had neither shoes nor shirt. "A slave who was made to live so," the sophist Antiphon said, "would run away." This self-imposed life of hardships was the price of his spiritual independence. His message was variously received. Some of those whose false pretensions were exposed by his trenchant criticizing regarded him with ill will; many thought him an officious busybody. Among the younger men, many merely thought it good sport to see their elders silenced. Others (Xenophon says that this was the case with Alcibiades and Critias [*qq.v.*]) deliberately attached themselves to him for a time "for private ends," believing that to learn the secret of so acute a reasoner would be the best preparation for success

in the law courts, the council, and the assembly. Others sincerely hoped by associating with him to become good men and true, capable of doing their duty by house and household, by relations and friends, by city and fellow citizens.

Finally, there was an inner circle who entered more deeply into Socrates' principles and transmitted them to the next generation. But these were not "disciples" united by a common doctrine. Socrates finally repudiated all claim to have "disciples." The bond of union was a common reverence for a great man's intellect and character. It was, in the main, this group who were collected around Socrates on the day of his death; many of them, for instance Euclid of Megara and the young Theban Pythagoreans, Cebes and Simmias, were foreigners from states which had been enemies of Athens in the Peloponnesian War.

The Accusation and Its Causes.—The explanation of the attack made on Socrates is simple. He had been on terms of close friendship with the two men whose memories were most obnoxious to the democrats: Critias, the fiercest spirit among the extremists of the "Terror" of 404; and Alcibiades, whose self-will had done so much to bring about the downfall of the Athenian empire. The charge of "educating Alcibiades" was made prominent in the pamphlet written a few years after the trial by the sophist Polycrates, in justification of the verdict. More than half a century later, the orator Aeschines reminds his audience that Socrates had been put to death because he was believed to have educated Critias. In point of fact, it was absurd to make Socrates responsible for the ambitions of Alcibiades, and, as he reminded his judges, he had disobeyed an illegal order from Critias and his colleagues at the risk of his life. But it is natural that he should have had to suffer for the crimes of both men, the more so because he had been an unsparing critic of democracy and of the famous democratic leaders and furthermore had not, like the advanced democrats, withdrawn from Athens during the "Terror."

Socrates was, in fact, suspected of using great abilities and gifts to pervert his younger associates from loyalty to the principles of democracy, and the convinced democrats who had recovered the city in 403 were unwilling, as J. Burnet has said, "to leave their work at the mercy of reaction." That they took no steps for four years is probably explained by the state of complete confusion and congestion into which the disorders of 404 had thrown the law courts. The motives of Anytus, an upright, unintelligent democrat, are thus quite explicable. From his point of view, Socrates would be at the best a moderate oligarch, and democrats who remembered the career of Theramenes (*q.v.*) could not be expected to make a fine distinction between the moderate oligarch and the traitor.

The real grounds for the attack could not be disclosed in the indictment, since the amnesty which had terminated the struggle of 404–403, and of which Anytus himself had been a main promoter, covered all offenses committed before the archonship of Eucleides (403). Hence the charge had to be couched in the form of a vague accusation of "corruption of the young." Probably for the same reasons Anytus was ashamed to appear as the principal in the matter and put forward the obscure Meletus, who might venture on "indiscretions" more openly. If Meletus was the same person who prosecuted Andocides (*q.v.*) in 400 on the same charge of "impiety," and if, as is not unlikely, he is the real author of the speech *Against Andocides* ascribed to Lysias, he must have been a half-witted fanatic, and this may explain why the charge of irreligion was added. The real nature of this "irreligion" appears never to have been explained. Xenophon suggests that the allusion was to the "Divine sign" but this cannot be correct. It is clear from Plato's *Apology* that Meletus said nothing about the "sign" at the prosecution, and that Socrates is speaking with his "usual irony" when he pretends to guess that the mention of "religious novelties" in the indictment referred to it. In the *Apology*, Socrates says that the prosecution is, no doubt, relying on memories of Aristophanes' *The Clouds*, where he had been made to talk "atheism" as part of the burlesque on men of science.

But there must have been more behind the charge, and it seems likely that Burnet is right in reminding us that the prosecution of Andocides revived the old scandal of the "profanation of the mysteries," which had thrown Athens into a ferment on the eve, 416–415, of the Sicilian expedition. The two chief victims, Alcibiades and his uncle Axiochus, were both among the intimates of Socrates, and there is reason to think that others of his friends were affected. If this is what lay behind the charge, it can be understood why its real meaning seems never to have been explained. In view of the terms of the amnesty, the matters in question were not really within the competency of the court.

Socrates himself, in the account of Plato, who was present at the trial, treats the whole matter with contempt. His defense consists in narrating the facts of his past life, which proved that he was equally ready to defy the populace and the Thirty in the cause of right and law, and in insisting on the reality of his mission from God and his determination to discharge it, even at the cost of life. The prosecutors had no desire for blood. They counted on a voluntary withdrawal of the accused from the jurisdiction before trial; the death penalty was proposed to make such a withdrawal certain. Socrates himself forced the issue by refusing at any stage to do anything involving the least shade of compromise. The prosecution had raised the question whether he was a traitor or, as he held himself to be, an envoy from God; Socrates was determined that the judges should give a direct verdict on the issue without evasion. This is what makes him a martyr, but also what forbids us to call Anytus a murderer.

Doctrine and Method.—Socrates was a man of the Periclean age, and the Periclean age witnessed one of the periodical "bankruptcies of science." Cosmological speculation, which had been boldly pursued from the beginning of the 6th century, seemed by the middle of the 5th to have led to a chaos of conflicting systems, each of which could establish only one point, that all its rivals were wrong. Parmenides (*q.v.*) of Elea had apparently cut away the ground from science by showing that the real world must be quite unlike anything our senses reveal to us, and that, consequently, the method of cosmology, interpretation of the world by analogies from familiar sensible experiences, is inherently fallacious. His pupil Zeno (*q.v.*) of Elea seemed to have shown that even the postulates of mathematics are mutually contradictory.

Science, then, seemed impossible, and that was why the ablest men of the generation before Socrates, such as Protagoras and Gorgias, turned away from the pursuit of it and tried to find a use for the intellect in professions that concerned themselves, not with the discovery of truth, but with making a success of human life (*see* SOPHISTS). "Probability is the very guide of life," and in practical matters "useful" points of view may be attainable, even if scientific certainty is beyond our reach. According to the narrative of the *Phaedo*, Socrates, as a young man, began with an experience typical of his age. He was enthusiastically interested in "natural science," and familiarized himself with the various current systems, being especially interested in the contrast between the old Milesian type of cosmology with its flat earth and the Italian type with its spherical earth. He was also interested in the mathematical puzzles raised by Zeno about "the unit" (*i.e.*, the problem of continuity). He discovered, to his distress, that though each authority was quite sure that the views of the others were wrong, none of them could give any proof that his own were right.

There was a complete lack of critical method. For a moment Socrates hoped to find salvation in the doctrine of Anaxagoras (*q.v.*) that "mind" is the source of all cosmic order, since this seemed to mean that "everything is ordered as it is best that it should be," that the universe is a rational teleological system. But on reading the book of Anaxagoras, he found that the philosopher made no effective use of his principle; the details of his scheme were as arbitrary as those of any other.

The Socratic "Hypothesis."—After this disappointment, Socrates decided that he had "no head for physics" and must fall back on his own mother wit. Accordingly he resolved from then on to consider primarily not "facts" but *logoi*, the "statements" or "propositions" that we make about "facts." His method would be to start with whatever seemed the most satisfactory "hypothesis," or postulate, about a given subject, and to consider the consequences that follow from it. So far as these consequences proved

to be true and consistent, the "hypothesis" might be regarded as provisionally confirmed; if they were false or mutually inconsistent it would be discredited. But it would have to be a strict rule of method not to confuse inquiry into the consequences of the "hypothesis" with proof of its truth. If the question of its truth were raised, the issue could be settled only by deducing the initial "hypothesis" as a consequence from some more ultimate "hypothesis" which both parties to the dispute were content to accept. The method, still familiar to us as that of true science, is manifestly suggested by reflection on the antinomies of Zeno, whom Aristotle called the creator of "dialectic" and whom Plato, in the *Parmenides*, afterward described as meeting Socrates in the youth of the latter.

The Doctrine of Forms.—According to Plato, Socrates next proceeded to take it as his own fundamental "hypothesis" that every term (such as "good," "beautiful," "man") which has a single unequivocal denotation directly names a single selfsame object of a kind inaccessible to sense perception and apprehensible only by thought. Such an object Socrates calls an *idea* or *eidos*, that is, a form (*q.v.*). The sensible things on which we predicate beauty, goodness, humanity, have only a secondary and derivative reality. Strictly speaking, we must not say that they *are* this or that, but only that they *become* this or that for a time, in virtue of the temporary "presence" to them of the corresponding form, or, as it is also expressed, in virtue of their "participation" in the form. A sensible thing, in fact, is simply a temporary complex of forms.

In the *Parmenides* of Plato Socrates is made to expound this doctrine to the great philosophers Parmenides and Zeno as his solution of the standing puzzle of the one and the many. This is the doctrine of forms as it is stated in the *Phaedo* and *Republic*. Though it is quite different from the version of the doctrine ascribed by Aristotle to Plato, scholars in the 19th century usually assumed that it is an earlier version of that doctrine consciously devised by Plato after the death of Socrates. The chief argument for this view is based upon the observation of Aristotle that Socrates rightly "did not separate" the universal from the particular (*Met. M*, 1078 *b*30) as, it is apparently implied, Plato did. It is, however, not clear that Aristotle means by this, what he never says expressly, that Socrates did not teach the doctrine ascribed to him in the *Phaedo*. He might equally mean that the doctrine of the *Phaedo* does not itself involve the kind of "separation" of the universal from the particular to which he objects in what he describes as the Platonic theory, and, since the *Phaedo* is one of the Platonic dialogues to which he most frequently alludes, it is strange that he should never have said that it misrepresents the historical Socrates on a capital point, if he really thought so.

On the other side, the doctrine is expressly said in the *Phaedo* to be a familiar one which Socrates "was always" repeating, and it is hard to believe that Plato could have made such a statement about a speculation of his own, especially as most of the personages of the *Phaedo* were certainly still alive long after the dialogue was written. It is hard to see what could be the point of such a mystification, and harder to understand how its author could have expected it to be successful. Of course, we can be guided only by considerations of probability. If we think the probabilities are against the view that credits Plato with deliberate mystification, we must be prepared to admit the possibility that he is also reproducing the thought of Socrates in the further development of the *Symposium* and *Republic*, where we hear of a supreme Form, that of Beauty, or Good, the vision of which is the far-off goal of all intellectual contemplation. We may fairly suspect that the thought of Socrates is undergoing development in the mind of Plato, but it will be natural to regard the development as, in the main, unconscious, and to recognize that no complete separation of the Socratic and the Platonic in the result is possible. (*See* also PLATO.)

Logical Method.—It is certain that on the logical side the thought of Socrates proceeded "as if" the doctrine of forms expounded in the *Phaedo* were its point of departure. Both Plato and Xenophon bear out the remark of Aristotle that Socrates may fairly be credited with two things, "inductive arguments" and "universal definitions" (*Met. M*, 1078 *b*27). The "universal definition" is an attempt to formulate precisely the meaning of a universal significant predicate, that is, to apprehend what the *Phaedo* calls a form; and it is from the practice of Socrates, who aimed at the clarification of thought about the meaning of moral predicates as the first indispensable step to the improvement of practice, that the theory of logical division and definition, as worked out in Plato's later dialogues and the logical treatises of Aristotle, has arisen.

The "inductive arguments" mean the characteristic attempts to arrive at such formulations by the consideration of simple and striking concrete illustrations familiar to us from both Xenophon and Plato, the perpetual arguments about "shoemakers and carpenters and fullers," which the fashionable speakers in Plato profess to think vulgar. Induction, on this view of it, is not regarded as a method of proof. Its function is that of suggestion; it puts the meaning of a proposed "definition" forcibly and clearly before the mind. The justification of the definition, then, has to be sought in a consideration of the satisfactoriness of the "consequences" which would follow from its adoption. Socrates himself sought for his "definitions" principally in the sphere in which he was most interested, that of conduct, private and public. As Aristotle says, he concerned himself with the "ethical," character and conduct, not with "nature" at large. This is what Cicero means by saying that he "brought down philosophy from heaven to earth."

Ethics and Politics.—Before Socrates, cosmology had been the chief topic of interest; after him, the central problem of philosophy was to formulate a rule of life. With him the "practical use of reason" comes by its rights. In this respect Socrates stamped on philosophy a character which it has never lost. The main outlines of his philosophy of conduct are fortunately quite certain, and could be discovered if we had no more material than the Platonic *Apology* and the *Memorabilia* of Xenophon. As the *Apology* tells us, the specific message from God which Socrates brought to his fellowmen was that it is the great business of life to practice the "care" or "tending" of one's "soul," to "make one's soul as good as possible," and not to ruin one's life, as most men do, by putting care for the body or for "possessions" before care for the "soul."

The thought which is here fundamental is that of the "soul" or *psyche* as that which is most truly a man's self. In Greek literature, down to the end of the 5th century, we can trace two main senses of the word *psyche*. In the first place, *psyche* means "the breath of life" which a man parts with in dying. It is this which, in popular superstition, is left as a mere "ghost," or "shade," when the man "himself," his body, has perished. In earlier Ionian science this is identified with the "air" which a man inhales so long as he is alive. Secondly, in circles influenced by the Orphic religion, the soul is thought of as something which has a destiny beyond the grave, but this, too, is something different from the self. It is a sort of stranger inhabiting the body, but having little to do with the conduct of normal life. It "sleeps while the body is active, but wakes when the body sleeps," and reveals itself chiefly in dream and trance. From the beginning of the 4th century we find *psyche* coming at last to mean what "soul" means to us, the normal waking personality, the seat of character and intelligence, "that," as Socrates says in Plato, "in virtue of which we are called wise or foolish, good or bad," and as this usage of the word first appears in writers whom we know to have been influenced by Socrates (Isocrates, Plato, and Xenophon), we may fairly ascribe it to his influence. The thought now works out thus. The soul *is* the man (in the later Academic formulation a man *is* "a soul using a body").

Our happiness or well-being, then, depends directly on the goodness or badness of the soul. It is no happiness to possess health, or strength, or wealth, unless we know how to *use* these advantages rightly. If we use them wrongly, they will only be so many means to misery. The reason so few achieve happiness is not that men do not wish to be happy. No one ever wishes for anything but true good, that is, true happiness, but men miss their happiness, in spite of the universal wish for it, because they do not *know* what it is. They mistake for real good things which are not really good (*e.g.*, unlimited wealth or power).

In this sense, "all wrong-doing is involuntary." The first and fundamental requisite for happiness, then, is that men should *know* true good and not confuse it with anything else. The good state of the soul is precisely that state in which it never makes the mistake of taking anything to be good when it is not really good. To "make one's soul as good as possible" thus means to attain the knowledge of good which will prevent us from *using* strength, health, wealth, opportunity, wrongly. If a man has this knowledge, he will always act on it, since to do otherwise would be to prefer known misery to known happiness, and this is impossible. "*All* the virtues are one thing," *knowledge* of good, and all "vice" is one thing, ignorance of true good.

"Popular" goodness—what passes currently as virtue—is mostly illusory, because it is mainly a matter of habit, not of assured conviction about good. It breaks down under temptation; but if a man really knew that, for instance, to commit a crime is worse than to suffer loss or pain, or death, no fear of these things would lead him to commit the crime. The professional sophist, again, claims to be able to teach "goodness," but the claim is shown to be unfounded by the very fact that the sophist treats "goodness" as though it were a neutral "accomplishment" that might be conveyed by mere instructions. Now an accomplishment, or "art," can always be put to either of two uses, a good or a bad, as the physician, for instance, can use his professional knowledge to cure or to kill.

Knowledge of good is the one knowledge of which it is impossible to make an ill use; the possession of it is a guarantee that it will always be used aright. Thus Socrates becomes, as against the relativism of Protagoras, the founder of the doctrine of an absolute morality based on the conception of a felicity which is the good, not of Athenians or Spartans, or even of Greeks, but of man as man. It is not in virtue of our allegiance to a particular city, nor even of our place in a particular historical civilization, but in virtue of our universal humanity, that we have the task of "making the soul as good as possible," or, as Socrates also said, in language influenced by Pythagoreanism, "making it like God."

Politics, from this point of view, does not differ in principle from ethics. The business of the statesman also is the "tending" of souls, though his task is to aim at making, not only his own soul, but the souls of all his fellow citizens "as good as possible." The knowledge of good is also the "royal" science or science of governing, the foundation of all statesmanship. The radical vice of ancient democracy, according to Socrates, is that of not demanding evidence of any special knowledge in its leaders; it suffers the destinies of society to be in the hands of men without true insight. Partly this means that by not demanding intellectual qualifications for office, democracy surrenders the control of affairs into the hands of men with no adequate expert knowledge.

But this is only a minor part of Socrates' indictment. His main criticism is that though in some departments, at least, the democracy refuses to take the advice of anyone but a qualified expert, on the question of the morality and justice of a proposed policy it treats any one citizen's opinion as of equal value with another's. Even a Themistocles or a Pericles plainly had no knowledge of true statesmanship, as we see from the fact that they neither taught the principles of it to their sons nor had them taught these principles by others, and if we look at the actual achievements of these men we can see that they were, so to say, good "body-servants" of the "people"; they gave it the things that tickled its taste, such as a navy and a commerce; they were no "physicians of the body politic," for they did not promote "righteousness and temperance," the spiritual health of the community. That is, they measured national greatness by wealth and empire, not by character. According to Plato, Socrates maintained that he himself, who abstained all through from active politics, was the one Athenian of the time who deserved the name of statesman. He deserved it because he understood, as the men of action did not, that national, like individual felicity, depends on the knowledge of good which inevitably leads, where it is possessed, to the action which makes the soul "as good as possible."

Plato's *Republic* may fairly be said to be, on its political side, a picture of the life of a society in which the whole system of social and economic life is based on this Socratic conviction that "politics" is the application to the community at large of the principle that knowledge of the absolutely good is the necessary and sufficient condition of well-being.

How far any of the special regulations of the *Republic* embody actual convictions of Socrates is more than we can say, though it is significant that the *Aspasia* of Aeschines represents Socrates as maintaining one of Plato's "paradoxes," the capacity of women for war and politics.

The Socratics.—The thought of Socrates has, in the main, been made fruitful for subsequent ages by being taken up and continued in the lifework of Plato. A more temporary influence was exercised by certain other members of the group of Socratic men whom it has become customary to speak of as the "minor" Socratics. The most important of them are Antisthenes of Athens and Euclid of Megara, with whom the Cynics and the Megarian School (*qq.v.*) of the 4th and early 3rd centuries are historically connected. With them it is usual also to mention Aristippus of Cyrene, often still spoken of as somehow connected with the Cyrenaics (*q.v.*) of the early 3rd century.

It is probable, however, that the current accounts exaggerate the closeness of the connection between these men and the later schools. Aristippus figures in Xenophon's *Memorabilia* simply as a luxurious and refined man of the world who makes it his rule of life to extract personal enjoyment from existence, sitting loose to all attachments which might interfere with his ease and not allowing himself to take root anywhere. The later anecdotes about him bear out this representation. There is no good evidence that he had a philosophy or originated a school. Aristotle ascribes no doctrine to him and never mentions a "Cyrenaic" school of hedonists, though he could hardly have avoided doing so in his discussions of hedonism in the *Nicomachean Ethics* if he had known of one. Plutarch expressly describes the Cyrenaics as contemporaries of Epicurus, and all the names of members of the school known to us belong to the time of the successors of Alexander the Great. The one point of doctrine common to them appears to have been that they rejected the notion of a good more permanent than the pleasure of the moment. The supposed connection of Aristippus with them seems to be based on a confusion with his grandson of the same name, who, according to Eusebius, reduced his grandfather's practice to theory.

Euclid of Megara was a friend both of Socrates and of Plato, who temporarily took refuge with him after the death of Socrates, and, at a later date, dedicated the *Theaetetus* to him. All that we know of his teaching is that he held to the monism of Parmenides, maintaining that nothing is real except "the One," which is also called "wisdom," "intellect," and "God" (Diogenes Laërtius, ii, 106). The mention of "wisdom" as a synonym for "the One" seems to reveal the influence of Socrates. Most of our notices of Megarians deal with men of a later time, Eubulides, a contemporary of Aristotle, Diodorus Cronus, and Stilpo. These men were pugnacious formal logicians famous for their rejection of the notion of "possibility" which is so fundamental in the Aristotelian philosophy. According to them, nothing is possible except the actual. Aristotle resented the criticism so keenly that "sophist" in his terminology appears to be regularly equivalent to "Megarian logician." It is not clear how these "eristics" or disputators are connected with the monism of Euclid. There are reasons for supposing the puzzling antinomies of Plato's *Parmenides* to be a parody of Megarian logic.

Antisthenes was a friend of Socrates of long standing, with a marked individuality of his own, and a voluminous writer much admired for his style. He does not appear to have been a "disciple," though he was personally attached to Socrates, and particularly admired his strength of will and mastery of his passions. In philosophy he is chiefly known for two things, his denial of the possibility of making judgments in which the predicate and subject terms are nonidentical, and his insistence in ethics on the simplification of life by the reduction of our wants to an indispensable minimum.

In virtue of the latter he was commonly regarded as the founder of Cynicism and it is certain that he personally influenced the famous Diogenes and that the later Cynics were in the habit of regarding him as a model man. But it is not clear either that the Cynics of the 4th century were a "sect" or "school" in any real sense of the words, or that the nickname "dog" was ever given to anyone before Diogenes. It was believed in later antiquity that there was a personal feud between Antisthenes and Plato, and it seems certain that one of the works of Antisthenes, called *Sathon*, was a virulent personal attack on Plato. But the ingenuity spent in the 19th century on discovering polemical allusions to Antisthenes in Plato's dialogues seems to have been mostly wasted. According to Plato, the logical paradox that "contradiction is impossible" was maintained by numerous persons in the days of Socrates. Hence it seems unreasonable to detect special allusions to Antisthenes in the frequent references to this paradox in the dialogues.

(A. E. TA.; X.)

SOCRATES (*c.* 380–*c.* 445), ecclesiastical historian, was a Christian lawyer, born and bred in Constantinople, who supplemented the latter part of the ecclesiastical history of Eusebius of Caesarea (*i.e.*, from A.D. 306 to 324) and continued it to his own day. His work extends to A.D. 439; it is arranged in seven books corresponding to the emperors ruling in the Eastern Empire (Constantine I, Constantius, Julian and Jovian, Valens, Theodosius I, Arcadius, Theodosius II). The extant history is a second edition. Socrates says that in the first two books he had previously followed the ecclesiastical history of Rufinus (A.D. 403) too closely, but that he had rewritten them after having become acquainted with the writings and documentary collections of Athanasius.

He had little knowledge of the Western church, but had access to good written sources for the history of the church in the Eastern Empire; these he supplemented from oral tradition and, where possible, eyewitness accounts. Besides Eusebius, Rufinus and Athanasius he drew upon the important collection (no longer extant) of conciliar proceedings made by Sabinus, bishop of Heraclea. An unsettled problem is the extent of his debt to the lost history of Gelasius of Caesarea (d. 395). Socrates was sympathetic toward, though not himself a member of, the schismatic Novatianist church in Constantinople and derived information from its records and traditions. With regard to eyewitnesses, however, his precepts were better than his practice, for he could not resist an anecdote; as a result, the earlier part of his ... where he is dependent almost entirely on written evide... trustworthy than the later.

Straightforward and sensible, but without technical skill ... torical investigation, he made some bad mistakes, especially chronology (*e.g.*, over the Council of Sardica). He had no ... found insight, but his layman's outlook is interesting: a healthy anticlericalism (he dislikes hierarchical pride and ... tentiousness), tolerance of divergent ecclesiastical ... position to coercion in religion, an attitude to heresy ... liberal for his time (though often lacking in theol... tion) and a recognition that church history must be se... general context (though here also his perception of p... better than his practice). Loyalty to Constantinople may accou... for his attacks upon the Alexandrians Theophilus and Cyril ... his judgment of John Chrysostom, bishop of Constantinople, is reserved and partly unfavourable.

Whatever his faults, Socrates provided what remains an indis... pensable framework for the ecclesiastical history of the period he covers, and preserved many documents of the first ... His history served as the foundation of a parallel work by his contemporary Sozomen (*q.v.*) and was later excerpted, together with the histories of Sozomen and Theodoret, to make the Latin ... *toria Tripartita* of the monk Epiphanius, from which the ... church of the West took much of its knowledge of early Christianity.

[illegible]

SÖDERMANLAND, [illegible] east [illegible] 2,61 sq.mi. (6,831 sq.km.). The relief is broken [illegible]

the Södertälje ship canal to the east of it; this bypasses Stockholm in linking Lake Mälar with the Baltic. Although not a rich district, it gains through being crossed by trunk railways and roads.

Nyköping, the county town, lost iron-ore shipment traffic to Oxelösund, which is less icebound. (A. C. O'D.)

SÖDERTÄLJE, a town of Sweden, in the *län* (county) of Stockholm, lies between a bay of Mälaren Lake and the Baltic Sea, there connected by the Södertälje Canal (1819), 20 mi. SW of Stockholm. Pop. (1960) 33,014. In and around the town are St. Ragnhild's Church (believed to date from 1100), the town hall (1735), Tveta Church, Gripsholm Castle, and an open-air museum on the Torekällberget (hills). The town was founded in the 10th century A.D. and damaged by fire in 1390, 1650, and 1719. In the 19th century it was a well-known spa and bathing resort; it is now dominated by its industries, which include the manufacture of trucks and buses, metal goods, milk separators and milking machines, medicines, light concrete, and tobacco products. The town is a rail and road junction on the routes from Stockholm to Malmö, Göteborg, and Oslo, Nor. (F. Vo.)

SODIUM is a member of the group of chemical elements known as the alkali metals (other members are lithium, potassium, rubidium, cesium, and francium). Metallic sodium is a soft, silvery white material that tarnishes rapidly in air because of the formation of a film of the oxide. Sodium is very widely distributed in the form of its compounds, of which ordinary salt, or sodium chloride, is the most familiar. The chemical symbol for sodium is Na (from the Latin *natrium*), its atomic number is 11, and its atomic weight is 22.9898. Sodium has only one stable and naturally occurring isotope, of mass number 23, but radioactive isotopes with mass numbers 20, 21, 22, 24, and 25 have been prepared. Sodium-22, a positron emitter with a half-life of 2.6 yr., is often used as a radioactive tracer for sodium. Sodium-24 (a beta emitter with a half-life of 15 hr.) is, because of its short half-life, procurable only by laboratories reasonably close to the production machines.

The Metal.—Many of the physical and chemical properties of sodium may be explained by the electronic configuration of the sodium atom: $1s^2, 2s^2, 2p^6, 3s^1$. The inner ten electrons constitute a rare gas configuration and are not involved in the usual chemical reactions of sodium. Only the single 3s electron acts as a "valence electron"; it is removed very easily to yield an Na^+ ion. In the metallic state the valence electrons of the assembled sodium atoms can migrate in an electric field; hence the metal exhibits a very high electrical conductivity. Since there are not enough valence electrons to bind the atoms firmly to their neighbours in the solid state, sodium is soft (it may be readily sliced with a knife) and it has a low melting point (97.83° C) and a low heat of fusion (0.622 kg.cal/mole). Sodium boils at 883° C (with a heat of vaporization of 22.2 kg.cal/mole) to give a vapour consisting largely of monatomic sodium. A small fraction of the atoms in the vapour are dimerized as Na_2 molecules, which have a dissociation energy of 19 kg.cal/mole. The standard potential of a sodium electrode in aqueous solution is 2.714 volts relative to the standard hydrogen electrode:

$$Na = Na^+_{(aq)} + e^- \qquad E^\circ = 2.714 \text{ volts}$$

This potential places sodium among the most powerful reducing agents in aqueous solution and explains why sodium reacts vigorously with water to give hydrogen and a solution of sodium hydroxide:

$$Na + H_2O \longrightarrow Na^+ + OH^- + \tfrac{1}{2}H_2$$

The apparent radius of the sodium ion in its compounds is 0.98 Å (Ångström units), or 0.98×10^{-8} cm.

The ionization potential of sodium (the energy required to completely remove the 3s electron from the gaseous atom) is 5.138 electron volts. However, there are many lower energy levels to which the valence electron can be excited, corresponding to excited states of the sodium atom. Spontaneous transitions among these energy levels give rise to the emission spectrum. A very prominent pair of lines in the spectrum (the Fraunhofer D line) at 5896 and 5890 Å accounts for the bright yellow colour of both the sodium flame and the sodium vapour lamp. The flame colour is the basis of a very sensitive analytical test for sodium.

Sodium forms an amalgam with mercury with almost explosive violence. A sodium-lead alloy is often used in place of metallic sodium as a reducing agent or a drying agent. A eutectic alloy of 22.7% sodium and 77.3% potassium (called "NaK") is liquid down to −12.5° C. Sodium, like the other alkali metals, has the remarkable property of dissolving without appreciable reaction in solvents such as liquid ammonia and amines to form highly conducting blue solutions. In these solvents the sodium ionizes to the Na^+ ion and the blue solvated electron.

The first isolation of sodium (by Sir Humphry Davy in 1807) was achieved by the electrolysis of fused sodium hydroxide. A modification of this method, the Castner process, was long used as a commercial method for preparing the metal. Most sodium is now prepared by the Downs process, in which a fused mixture of sodium chloride and either calcium chloride or sodium carbonate is electrolyzed to yield chlorine as well as the metal. Pure molten sodium chloride is not used because at the melting point of sodium chloride (801° C) the vapour pressure of sodium metal is dangerously high and sodium is appreciably soluble in the fused salt. With the salt mixtures, the electrolysis cells may be operated in the vicinity of 600° C.

Metallic sodium is used in the manufacture of the peroxide (Na_2O_2), cyanide (NaCN), amide ($NaNH_2$), hydride (NaH), and borohydride ($NaBH_4$), all of which are of technical importance. It is extensively used as a reagent in synthetic chemistry. The sodium-lead alloy is used in the manufacture of tetraethyl lead, a common constituent of antiknock gasoline. Sodium, like the other alkali metals, possesses to a marked degree the photoelectric effect (emission of electrons when exposed to light) and was once used in the manufacture of photoelectric cells. On account of its relatively high heat capacity and high heat conductivity sodium is used as a heat transfer medium. In some types of atomic reactors, molten sodium is used to transfer heat from the core of the reactor to a water boiler for steam generation.

Compounds.—Because of its intense chemical activity sodium is never found as the metal in nature; in the form of compounds however, it is widely distributed. The earth's crust contains about 2.8% sodium in the combined form, placing it sixth in order of abundance among the elements. Sodium chloride is exceedingly abundant and widespread, being the chief salt present in sea water besides occurring throughout the world in extensive deposits that probably owe their existence to the evaporation of prehistoric seas. Sodium chloride comprises about 80% of the dissolved matter in sea water. (For additional information on sodium chloride, *see* SALT; SALT DOME.)

Sodium carbonates are also widely dispersed in nature, forming constituents of many mineral waters and occurring as the principal saline components in natron or trona lakes, as efflorescences in Lower Egypt, Iran, and China, and as trona (urao) in Mexico, Colombia, and Venezuela. The solid crusts found at the bottom of the salt lakes of the Araxes plain in Armenia contain about 16% of carbonate and 80% of sulfate. In Colombia there occurs a double salt, $Na_2CO_3 \cdot CaCO_3 \cdot 5H_2O$ known as gaylussite. Enormous deposits of carbonates, mixed in some cases with sulfate and with chloride, occur in Wyoming, California, and Nevada. Vast areas of the steppes in Hungary contain sodium carbonate in the soil.

Natural sulfate occurs in an anhydrous condition as thenardite, Na_2SO_4, in Tarapacá province, Chile, and in the rock-salt deposits at Espartinas near Aranjuez, Spain. The world's largest known deposits of natural sodium sulfate are located in Saskatchewan. Hydrated sulfates occur at several localities in Spain and at Mühlingen in the Aargau canton of northern Switzerland; copious deposits of glauberite, the double sulfate of sodium and calcium are found in the salt mines of Villarrubia in Spain, at Stassfurt, Ger., and in Tarapacá, Chile, etc. A native nitrate of sodium is obtained in great abundance in Tarapacá and also in the province of Atacama in Chile; it was formerly imported into Europe in enormous quantities as cubic nitre for the preparation of saltpetre. Cryolite, a fluoride of aluminum and sodium, is mined extensively

in Greenland and elsewhere for industrial purposes.

These minerals form the principal natural sources of sodium compounds—the chloride as rock salt and in seawater being of such predominating importance as to outweigh all the others. But it is questionable whether, taken altogether, the mass of sodium they represent is as much as that disseminated throughout the rocky crust in the form of sodium feldspar (*i.e.*, as silicate of sodium) and in other sodium-containing rocks.

In its compounds, sodium always exists as a +1 ion. Its salts are generally very soluble in water; three exceptions are the fluosilicate, Na_2SiF_6; the antimonate, $NaSb(OH)_6$; and the zinc uranyl acetate, $NaZn(UO_2)_3(C_2H_3O_2)_9 \cdot 6H_2O$.

Sodium hydride, NaH, is a crystalline substance obtained by the direct reaction of hydrogen with sodium at 250° to 350° C. It burns when heated in air and reacts vigorously with water, giving one mole of hydrogen per mole of hydride:

$$NaH + H_2O \longrightarrow Na^+ + OH^- + H_2$$

The analogous reaction of sodium hydride with alcohols is valuable for the preparation of alkoxides:

$$NaH + ROH \longrightarrow NaOR + H_2$$

Sodium hydride reacts with methyl borate at elevated temperatures to form sodium borohydride, $NaBH_4$:

$$4NaH + B(OCH_3)_3 \longrightarrow NaBH_4 + 3NaOCH_3$$

Sodium borohydride is stable in alkaline aqueous solutions and is useful as a powerful reducing agent. Sodium borohydride is an important starting material in the preparation of diborane, B_2H_6.

Sodium monoxide, Na_2O, may be prepared by direct oxidation in the presence of excess metal. Reaction in an excess of oxygen yields chiefly the peroxide, Na_2O_2. In the industrial preparation of the peroxide, the oxidation proceeds stepwise, as follows:

$$2Na + \tfrac{1}{2}O_2 \longrightarrow Na_2O$$
$$Na_2O + \tfrac{1}{2}O_2 \longrightarrow Na_2O_2$$

If sodium peroxide is heated to about 450° C. in 300 atmospheres of oxygen, the superoxide, NaO_2, is formed:

$$Na_2O_2 + O_2 \longrightarrow 2NaO_2$$

The peroxide and superoxide are powerful oxidizing agents. Sodium peroxide reacts with carbon dioxide to liberate oxygen:

$$2Na_2O_2 + 2CO_2 \longrightarrow 2Na_2CO_3 + O_2$$

The last reaction found application during World War II and thereafter for the revivification of air in confined spaces such as aboard submarines and also aboard airplanes at extremely high altitudes.

Sodium hydroxide, NaOH, also called caustic soda, is manufactured by the electrolysis of a solution of sodium chloride, a process that results in the formation of the hydroxide and hydrogen at the cathode and chlorine at the anode. The overall cell reaction is

$$2H_2O + 2Cl^- = 2OH^- + H_2 + Cl_2$$

The electrolysis cell is constructed so as to prevent the interaction of the hydroxide and the chlorine, which give hypochlorite. In the Castner-Kellner process, a mercury cathode is used so that a sodium amalgam is formed. The cell is constructed so that the amalgam reacts with water to form a very pure hydroxide solution, which is then evaporated to give the dry product. (*See* also Alkali Manufacture: *Electrolytic Production of Caustic Soda.*)

Sodium amide, $NaNH_2$, is prepared by the direct reaction of sodium with ammonia:

$$Na + NH_3 \longrightarrow NaNH_2 + \tfrac{1}{2}H_2$$

Sodium amide is used in the preparation of sodium cyanide by reduction with carbon at red heat:

$$NaNH_2 + C \longrightarrow NaCN + H_2$$

Sodium amide finds considerable use in synthesis as a reagent for the introduction of amino groups into molecules, for dehydration and for dehydrohalogenation. Sodium amide reacts in liquid ammonia with nitrous oxide to form sodium azide, NaN_3:

$$2NaNH_2 + N_2O \longrightarrow NaN_3 + NaOH + NH_3$$

Sodium azide has the remarkable property of decomposing cleanly to its elements at 300° C:

$$NaN_3 \longrightarrow Na + \tfrac{3}{2}N_2$$

The manufacture of sodium carbonate, Na_2CO_3, also called soda ash, is treated under Alkali Manufacture: *Solvay Process of Soda Ash Manufacture.* The anhydrous salt is a colourless material having an alkaline taste and reaction due to the hydrolysis of the carbonate ion. When heated, the bicarbonate is converted to the carbonate:

$$2NaHCO_3 \longrightarrow Na_2CO_3 + CO_2 + H_2O$$

Of the sodium silicates the most important is the mixture known as water glass, which is formed by calcining a mixture of white sand, sodium carbonate and charcoal, or by dissolving silica in sodium hydroxide under pressure. It is a colourless sirupy liquid that is used in certain printing processes, as a cement for glass, porcelain, etc., as a fireproofing agent, and as a water softener.

The manufacture of common soda glass principally involves the high-temperature reaction of sodium carbonate, calcium carbonate and sand to give a glass of the following approximate composition: SiO_2, 71%–78%; Na_2O, 12%–17%; CaO, 5%–15%; Al_2O_3, 1%–4%. Such glass has a remarkable permeability to sodium ions. At room temperature, the mobility of sodium ions is sufficiently great in some glasses to permit the manufacture of a glass electrode for determining sodium ion concentrations in aqueous solutions.

SODOMA (Giovanni Antonio Bazzi, known as "Il Sodoma") (1477–1549), leading Italian painter of the early 16th century in Siena, was born at Vercelli, in Piedmont, in 1477. From 1490–97 he was apprenticed to G. M. Spanzotti, a minor Piedmontese artist, but was afterward much influenced by the great masters of the High Renaissance, the style of Leonardo da Vinci (whose work Sodoma must have seen in Milan and Florence) and later that of Raphael being particularly decisive in determining his mature style. He was invited to Siena in 1501 and subsequently spent the bulk of his working life there. He died in Siena on the night of Feb. 14–15, 1549.

Sodoma's earliest works of repute were painted between 1505 and 1508 in the Benedictine monastery of Monteoliveto Maggiore, near Siena, where he completed the series of scenes from the life of St. Benedict left unfinished by Luca Signorelli in 1498. As a result of these he was invited to Rome by the celebrated Sienese banker Agostino Chigi, and was employed by Pope Julius II in the Stanza della Segnatura in the Vatican. Although he was superseded by Raphael in 1509, some of his ceiling decoration remains, and Raphael included Sodoma's portrait as well as his own in the "School of Athens" painted in this same room. Sodoma's masterpiece in Rome is the fresco decoration of Agostino Chigi's bedroom in the Villa Farnesina, where his "Marriage of Alexander and Roxana" (probably 1511–12) vies as a decorative achievement with frescoes by the school of Raphael in the same villa.

Sodoma's career spanned the period of transition from High Renaissance to Mannerism, and his work echoes these main trends. He had, however, a peculiar gift for suggesting the sensuous beauty of the human form (a characteristic that probably endeared him to the Sienese), and an exaggerated, almost mystical, emotionalism that anticipates one aspect of the Baroque. The St. Catherine frescoes in S. Domenico, Siena (begun in 1526), the "Christ at the Column" and the "Descent into Limbo" (both mature works in the Pinacoteca Nazionale, Siena) show Sodoma's art at its

best and most typical, as also does the St. Sebastian (Pitti Gallery, Florence), where his considerable feeling for landscape can also be appreciated. Works in Pisa Cathedral relate to Sodoma's visit there in 1540 and are among the few documented works of his late years.

Vasari, who disliked Sodoma, makes the most of the unpleasant sobriquet by which he was known from 1512 onward. From what is known of Sodoma's life, however, the nickname is more likely in the first place to have been the result of a joke, but it was adopted by the artist himself, and is the name by which he is now generally known.

See R. H. H. Cust, *Giovanni Antonio Bazzi* (1906), who quotes relevant documents; L. Gielly, *Giovan-Antonio Bazzi* (1911).

SODOM AND GOMORRAH, two of the five "cities of the plain" in the Dead Sea region, the others being Admah, Zeboiim, and Zoar (Bela) (Gen. 13, 14, 19). Sodom and Gomorrah, cities of legendary wickedness, were destroyed by a rain of "brimstone and fire" (Gen. 19:24). Their most likely location is beneath the shallow waters of the southern end of the Dead Sea (*q.v.*). Several minor streams which flow into the Dead Sea from the east could have provided water for their support. The level of the sea has risen in historical times, owing to deposits of silt and to other factors. Confirmation of heavy settlement of population in this general location is provided by Bab edh-Dhrâ, which was once a place of pilgrimage and feasting located about 500 ft. above the Dead Sea Peninsula (Al Lisan) and was used by the inhabitants of the cities below. Jabal Usdum ("Mt. Sodom"), at the southwest end of the sea, reflects Sodom's name. Josephus (*Jewish War* iv:8:4) locates Zoar definitely at the Dead Sea's southern end. (E. D. Gr.)

SOEST, a town of West Germany in the *Land* (state) of North Rhine-Westphalia, Federal Republic of Germany, lies 30 mi. (48 km.) E of Dortmund by road. Pop. (1961) 33,304. Soest is in the middle of the fertile loess-covered tract of land known as the Soester Börde extending south from the Lippe River. The Grosser Teich ("great pond") in the town centre is fed by warm springs; an affluent of the Lippe rises there. The town is among the most charming in Westphalia, with a profusion of flowering trees, numerous timbered houses, and many old buildings. The remains of the surrounding walls include the Osthofentor gatehouse (1526). A 12th-century Roman Catholic cathedral (St. Patroclus) adjoins the Baroque town hall (1713), whose municipal archives include letters by Luther and Melanchthon and an important early Protestant theological library. The Wiesenkirche ("church in the fields") is one of the most beautiful Gothic churches in Germany and its pleasing stained-glass window (*c.* 1530) of the Last Supper is typically Westphalian. There was severe bomb damage in World War II, but restoration has taken place. The town is the market for the farm products of the Börde, and its industries include the production of sugar, storage batteries and lamp bulbs, wire, machinery, road making equipment, and clothing.

Soest was first mentioned (as Sosat) in documents in 836 and received its first charter in 1144. Until 1444 an appanage of the archbishops of Cologne, it became one of the most important Hanseatic towns. Its 12th-century code of municipal law (*Soester Schrae; jus susatense*) was one of the earliest and best.

SOEST, a municipality in the province of Utrecht, Neth., lies 28 mi. (45 km.) SE of Amsterdam by road. Pop. (1960) 28,370. It includes Soestdijk, where there is a royal residence; Soesterberg, with a military airfield; and Soestduinen. Soest town, founded in 1029, has a Gothic church dating from about 1400 and restored in 1959. Formerly an agricultural centre, the town is now largely residential, with many inhabitants commuting to the large towns, but has expanding light industries. (R. T.)

SOFA: *see* Chair and Sofa.

SOFIA (Sofiya), capital city of Bulgaria and centre of the *okrug* (district) of Sofia, is also an *okrug* in its own right. It is situated on two tributaries of the Iskur River, 1,800 ft. (550 m.) above sea level. Its climate is temperate continental and the temperature averages 1.9° C (35.4° F) in January and 20.2° (68.4°) in July. Pop. (1962) 713,308, not including suburbs.

Sofia is divided into six districts radiating from the centre of the city. There are some historical monuments, including the church of St. George, parts of which date from the 3rd century, which has been heavily restored, as also has the church of St. Sophia; and two mosques, one of which houses the archaeological museum. The domed Alexander Nevski cathedral was built in gratitude to the Russians who liberated Bulgaria in 1877–78. Notable also are the monument to the Russian army of liberation, the headquarters building of the Bulgarian Communist Party, and the mausoleum of the statesman Georgi Dimitrov (*q.v.*). As the centre of Bulgaria's cultural life Sofia houses the Kliment Ochridsky University, the Bulgarian Academy of Sciences, and the National Library, Theatre, Opera, and Art Gallery. There are many general education and vocational schools, health centres, and hospitals. Considerable rebuilding was done in Sofia after World War II. Traces of air raids in 1943 and 1944 were eliminated, new public buildings, houses, housing estates, hospitals, and schools were built, and parks and gardens were laid out. In 1961 a general plan was adopted for the development and reconstruction of the city. The chief industries are engineering and metallurgy, textiles, and food processing, with the manufacture of furniture, footwear, chemicals, and rubber goods. Thermal power stations supply the city with electricity and heat.

Sofia is the most important communications centre of Bulgaria, and is linked by road and rail to Belgrade, Istanbul, Athens, and Bucharest. There are regular air services to the larger towns of the country and to the principal cities of Eastern and Western Europe, as well as to Africa and Asia. City transport services are provided by a network of trams (streetcars), buses, and trolley-buses.

Sofia, known to the Romans as Serdica, grew and flourished during the reign of the emperor Trajan (2nd century A.D.) and until the 4th century. In the 5th century, as a province of the Byzantine Empire, it was devastated by the Goths, the Huns, and other peoples. Under Justinian (6th century) Serdica once more became an important town in the Eastern Empire and the original church of St. Sophia, which later gave its name to the town, dates from this time. The town was occupied by the Slavs in the 7th century. During the reign of King Krum in the 9th century Serdica was included in Bulgaria, and under the name of Sredets it was second in importance to Turnovo, capital of medieval Bulgaria.

It was under Byzantine rule from 1018–1185 and it was captured by the Turks in 1382. Many of the ancient buildings were destroyed and the town took on an Oriental appearance. In 1878 the Russian troops liberated Sofia and the constituent assembly which met in Turnovo in February 1879 chose the town as the capital of Bulgaria. This, together with its geographical situation, helped its rapid political, economic, and cultural development.

Sofia District (Sofia Okrug) has an area of 2,811 sq.mi. (7,281 sq.km.); pop. (1963 est.) 329,900. The city of Sofia lies on a plain surrounded by mountains. To the south are the Vitosha and Lyulin national parks. The district is famous for its mineral water springs and baths which are to be found in Sofia itself and in the suburbs of Gorna Banya, Knyazhevo, and Ovea Kupel, and the villages of Bankya and Pancharevo.

The church at Boyana, 6 mi. (10 km.) S of Sofia, is famous for its 13th-century wall paintings. The Iskur Dam lies 24 mi. (39 km.) SE of Sofia and Pancharevo Lake is at a distance of 9 mi. (14 km.). The waters of the dam are used for irrigation and power. (L. Di.)

SOFTBALL is one of the most popular participant sports in the United States. Though there are conflicting claims of invention and origin, it is generally agreed that softball, closely akin to baseball, developed from a game called "indoor baseball" which was first played in the gymnasium of the Farragut Boat Club in Chicago, Ill., in 1887. The game was introduced to the playgrounds and parks of Chicago and Minneapolis and later promoted throughout the country as a desirable outdoor game to be played in small public park and school playgrounds. It became known

in the United States by various names such as kitten ball, mush ball, diamond ball, indoor-outdoor and playground ball. Since there were wide variances in playing rules, size and type of playing equipment, and lack of uniformity as to dimensions of the playing field, a need developed to secure a uniform code of rules. In certain states, particularly Minnesota, Wisconsin, Florida and Colorado, the game rapidly progressed; playing rules were made more uniform and improved equipment was developed by manufacturers.

At the National Recreation Congress in Springfield, Ill., in 1923, a rules committee was appointed by Joseph Lee, a United States pioneer in recreation. The Lee committee was later enlarged to form the International Joint Rules Committee of Softball, which came to include representatives of a number of organizations which promote and sponsor softball. The committee was formed to gain general acceptance of and to publish and circulate a standard set of rules; to study the game in order to recommend changes in rules that would benefit the largest number of players; and to cooperate with manufacturers of sporting goods to secure standard and satisfactory equipment.

The Amateur Softball Association of America, organized in 1932, came to be the recognized governing agency for promotion and control of organized national competition. It became a member of the Amateur Athletic Union, the U.S. Olympic Commission, the National Recreation Association, and the International Softball Federation. Through its metropolitan, state and regional organization, it assumed responsibility for directing thousands of teams in competition, culminating in world championship tournaments for men and women, which have been held without interruption from 1933.

The International Softball Federation acts as a clearing centre for the softball organizations of more than 20 countries, including Australia, Japan, Argentina, England, and Canada.

Basically, the fundamentals of softball are the same as those of baseball (*q.v.*). Batting and fielding strategy are similar, but since the game is played on a much smaller area the action is much faster. It seldom requires more than an hour to complete seven innings for an official game.

A distinctive technique in softball is the underhand pitching. Special skills were soon developed in this art and pitchers developed baffling windups, followed by a release and throw of the ball that travels with a speed comparable to that of the overhand regulation baseball.

The regulation playing field for softball should have a clear, unobstructed area within a radius of 200 feet from home plate between the foul lines. It includes a diamond-shaped area with 60-ft. base lines. The pitching distance for men is 46 ft. and for women 40 ft. Bats must be round, not more than 34 in. long and not more than 2¼ in. in diameter at the largest part. The official softball is a smooth-seam ball, not less than 11⅞ in. nor more than 12⅛ in. in circumference, weighing between 6 and 6¾ ounces.

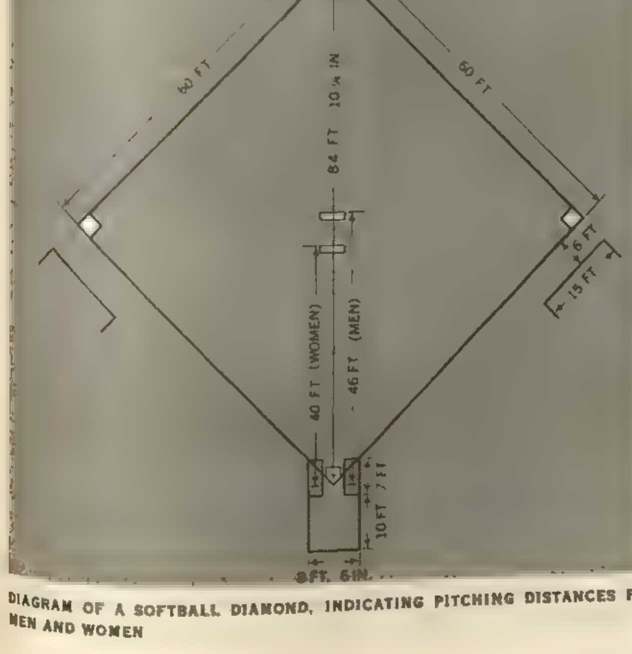

DIAGRAM OF A SOFTBALL DIAMOND, INDICATING PITCHING DISTANCES FOR MEN AND WOMEN

In summary, the rules for softball differ from those of baseball in the following respects:

(1) Softball base lines are 60 ft. long whereas baseball base lines are 90 ft.

(2) Softball pitching distance is 46 ft. compared with baseball's 60 ft. 6 in.

(3) The official softball is heavier and larger than a baseball.

(4) The official softball bat is shorter and lighter than a baseball bat.

(5) Softball games consist of seven innings whereas baseball games are nine innings.

(6) The chief difference in the pitching rules is that in softball the ball is delivered by an underhand motion to the batter with a follow-through of the hand and wrist past a straight line of the body before releasing the ball. The pitcher must pause for one second at the conclusion of his windup before delivering the ball.

(7) Base stealing is permitted in both games, but in softball the runner must keep contact with the base until the pitcher releases the ball on delivery to the batter.

Principal reasons for the great popularity of softball are that the game is played with speed, that it can be played at relatively low cost for equipment and uniforms, that it can be and is played by children and young and old men and women, and it has great appeal to spectators. Because of the smaller playing area, softball fans are continually thrilled by hard drives, bare-handed stops and fast throws. Close decisions are the rule on most plays. It gained wide acceptance, moreover, as an outstanding girls' and women's team sport; hundreds of women's softball teams are members of leagues which compete for honours in a world's championship tournament for women.

Softball also demonstrated its value as an informal recreational activity for industrial and business, church and school groups, at picnics and outings, and on neighborhood vacant lots and playgrounds.

One variation of the game, called slow-pitch, is played with a 14- or 16-in. ball on a diamond with 50-ft. baselines. Teams are organized for league play. (A. T. N.)

SOFT DRINKS, or nonalcoholic beverages, may be divided into two classes: carbonated beverages (sometimes called aerated waters) and still beverages (those without carbonation). With the exception of club soda or sparkling water, carbonated drinks contain sugar (or other sweetening) and edible acids, as well as artificial flavours or natural flavours derived from fruits, nuts, roots, herbs or other plant sources. Still beverages generally contain natural or artificial fruit flavours.

History.—Carbonated beverages and waters developed from European attempts to imitate the popular and naturally effervescent waters of famous springs, with primary interest in their reputed therapeutic values. The effervescent feature of the waters was recognized early as most important. Jan Baptista van Helmont (1577–1644) first used the term "gas" in his reference to the carbon dioxide content. Gabriel Venel referred to "aerated water," confusing the gas with ordinary air. Joseph Black named the gaseous constituent "fixed air."

Numerous reports of such experiments and investigations were included in the *Transactions* of the Royal Society of London in the late 1700s, including the studies of Stephen Hales, Joseph Black, David Macbride, William Brownrigg, Henry Cavendish, Thomas Lane, Joseph Priestley and others. Duplication of the waters of Bad Pyrmont, a spa in Germany near the city of Hameln, was one of the major objectives, probably because of the popularity of the spa and also because of the relatively simple nature of the mineral content of the waters there.

Priestley, who obtained "fixed air" for his experiments from a brewery near his house, published *Directions for Impregnating Water with Fixed Air* in 1772. For his reports concerning "fixed air" and the mixture of waters with it, but with special emphasis on the medicinal values shown by him to exist in artificially car-

bonated water (but since found to be illusory), he was awarded the Copley medal by the Royal Society of London in the following year.

Meanwhile, other European scientists were active in the field. Studies by Torbern Bergman, a Swedish chemist, were published in the reports of the Swedish Royal Academy of Science in 1775. Carl Wilhelm Scheele of Sweden was similarly engaged. Antoine Lavoisier, in France, identified the "fixed air" of Priestley as a combination of carbon and oxygen which he called *gas acide carbonique*. John Mervin Nooth, in England, developed special apparatus for the preparation of small quantities of the effervescent waters. His report appeared in the 1775 *Transactions* of the Royal society.

Improvements in the Nooth device were made by Jean Hyacinthe de Magellan in 1777, and in 1781–83 the English chemist Thomas Henry described apparatus for the production of carbonated waters on a commercial scale. Many others followed, and factories and bottling plants were opened in Geneva, Switz., Paris, London, Dublin, Ire., Dresden, Ger., and several other European cities during the period 1789–1821.

U.S. investigators also were interested in carbonated water and its health values. As early as the summer of 1807, in New Haven, Conn., Benjamin Silliman of Yale college began producing bottled soda water on a commercial scale, and he opened a public establishment for dispensing it. In Philadelphia, artificially carbonated waters were bottled and sold commercially by Joseph Hawkins, with machinery of his own invention. The firm was known as Shaw and Hawkins. Hawkins was issued a U.S. patent for preparation of imitation mineral waters in 1809, the first of record in this field.

The addition of flavourings to soda water to form the effervescent type of soft drink or carbonated beverage which became so widespread in America began early. Its exact origin is obscure, however. In 1768 Richard Bewley, in England, had introduced a form of soda water which he described as "mephitic julep," to be taken "with a draft of lemonade." He had followed a similar suggestion of Macbride concerning the medical efficacy of a mixture of fresh lime juice and alkaline salts taken as an effervescent drink.

Production Methods.—The basic ingredients in soft drinks are water, carbon dioxide, sugar, flavouring and, sometimes, artificial colouring.

Water, although most often taken from a safe municipal water supply, usually is given further processing to ensure uniformity of the finished product, because the amount of impurities in the municipal supply may vary from time to time. In some bottling plants the water-treatment equipment may consist simply of a sand filter to remove minute solid matter and an activated-carbon purifier to remove colour, chlorine and other tastes or odours. In most plants, however, water is treated by a process known as superchlorination and coagulation. In this process the water is exposed for two hours to a high concentration of chlorine as well as to a flocculant that removes such organisms as planktons (minute plants and animals); it is then passed through a sand filter and activated-carbon purifier.

Carbon dioxide gas gives the beverage its sparkle and tangy taste, and prevents spoilage. While it has not been proved that carbonation offers a direct medical benefit, carbonated beverages are used to alleviate post-operative nausea when no other food can be tolerated, as well as to ensure adequate liquid intake.

Carbon dioxide is supplied to the soft drink manufacturer in either liquid or solid ("dry ice") form, maintained under high pressure in heavy steel containers. As the pressure is released, the material changes into the gaseous form, in which it can be dissolved in water in quantities that vary with temperature and pressure. The amount of gas the water will absorb increases as the pressure is increased and as the temperature is decreased. Carbonation (of either the water or the finished beverage mixture) is effected by chilling the liquid and cascading it in thin layers over a series of plates in an enclosure containing carbon dioxide gas under pressure.

Flavouring sirups are made from sugar that is delivered from the refiner either in granulated form or as a 67% or 76% solution known as liquid sugar. The sugar is dissolved or diluted with processed water, and the desired flavouring substances are added. The resulting mixture is made more palatable by the addition of edible acids, principally citric acid, and its colour may be heightened by the addition of caramel (burnt sugar) or certified food-colouring materials. Large quantities of saccharin and other sweeteners are used for low-calorie beverages.

Two methods of producing the finished beverage are in use: either the sirup may be mixed with carbonated water prior to bottling or a precise amount of sirup may be measured into each bottle, after which the bottle is filled with carbonated water. In either case, the sugar content—51%–60% in the sirup—is reduced to 8%–13% in the finished beverage. The blending of sirups, mixing with carbonated water and filling of containers is carried out almost entirely by automatic machinery.

Most soft-drink producers use bottles of the returnable type, which reduce packaging costs, although some are using nonreturnable, "one-trip" bottles and metal cans. Before filling, returnable containers are thoroughly flushed with hot solutions of caustic soda or other alkalies for a minimum of five minutes, and then rinsed with potable water.

The production of still beverages involves ingredients and techniques similar to those used for carbonated beverages. However, since they lack the protection against spoilage afforded by carbonation, still beverages usually are pasteurized, either in bulk or by continuous flash pasteurization prior to filling or in the bottle. Some still beverages are sold in concentrated, frozen form, and these do not require pasteurization; however, they must be kept frozen until used. Since they are not under pressure, still beverages may be packaged not only in bottles and cans but also in cardboard cartons.

SOGA, the name of one of the great families of Japanese history, the first to usurp power and thus initiators of the tradition of dual government in Japan. In addition, Soga Iname was primarily responsible for introducing Buddhism into Japan, the first Buddhist temple in that country being in his home. Although descended from a collateral branch of the imperial family the Soga's history is obscure until Iname became minister in A.D. 536. His son Umako also became minister, and, beginning with the death of the emperor Bidatsu in A.D. 585, executed a series of maneuvers that culminated in the enthronement of his niece as empress Suiko in 592. Between that year and 643 the Soga held undisputed power in Japan and could claim three emperors and one empress as their creations. In 645 Soga Iruka and Soga Yemishi were assassinated by the Fujiwara family, who were to succeed them as regents, and with these murders Soga power ended. *See* also JAPAN: *History: The Clan Period.*

BIBLIOGRAPHY.—G. Sansom, *A History of Japan to 1334* (1958); J. Murdoch, *A History of Japan*, vol 1, ch. 4 (1926); R. Ponsonby-Fane, *History of the Imperial House of Japan* (1959). (J. A. HA.)

SOGA (BASOGA, WASOGA), an east African people of the Interlacustrine Bantu group who inhabit the area east of the Nile between Lakes Victoria and Kyoga. Although sharing a common basic culture, the Soga were divided among several small states Bugabula Bulamogi, Busiki, Luuka, Kigulu, Bukoli, Bugweri Butembe, Bunya, and Bunyuli. In economy, technology, and religion they resembled the Ganda (*q.v.*). In each state there were several dozen patrilineal clans, one of which held the rulership. The northern states were often tributary to the Nyoro (*q.v.*), while the Ganda dominated the south.

Since 1894 the Soga formed an administrative district of the Uganda (*q.v.*) protectorate which achieved full independence in 1962. In the 1960s they numbered about 600,000. *See* also BANTU (INTERLACUSTRINE). (L. A. FS.)

SOGDIANA, the ancient name for a region of Central Asia centring on the fertile valley of the Zeravshan, in the modern Uzbek Soviet Socialist Republic. The vast remains at Samarkand suggest that the region has been an important centre throughout history. The earliest settlement there belongs to the Iron Age of northeast Iran, in the first half of the 1st millennium B.C. Shortly

afterward, Sogdiana passed under Achaemenid rule and appears as a satrapy of Darius I. It was later attacked by Alexander the Great and may for a time have been included in the Bactrian Greek kingdom, until the invasions of Sakas and Yüeh-chih (*q.v.*) in the 2nd century B.C. Sogdiana remained a prosperous centre of population down to the Mongol invasions. Under the Samanid dynasty (9th–10th centuries) it became for a time the eastern focal point of Islamic civilization. (F. R. A.)

SŌGI (1421–1502), Buddhist monk and greatest master of *renga* (linked verse), the supreme Japanese poet of his age. Nothing definite is known about his career before 1457, but he was born of exceedingly humble stock. His later writings suggest that after serving as a Zen monk in Kyōto he became in his 30s a professional *renga* poet. In earlier times his humble birth might have militated against his career, but in the 15th century, when violent upheavals shook the traditional social order (*see* JAPAN: *History: The Development of Feudalism*), it was not an insuperable handicap. His teachers included not only provincial *renga* masters but court nobles, and though this training undoubtedly benefited his poetry it also exerted an inhibiting influence. Sōgi's own selection of his best work shows him at his most ingenious, in the aristocratic tradition; but his modern reputation is primarily accounted for by the deeply moving vein of his simpler and more personal poems.

Sōgi is known as a traveler-poet. His life for 40 years was divided between the capital and the provinces. From 1466 to 1472, a period when warfare ravaged Kyōto, he lived mainly in eastern Japan, associating with local potentates and composing manuals of *renga* for them. His return to Kyōto in 1473 ushered in his most fruitful period. His residence became the centre of literary activity in the city, and he compiled *Wasuregusa* and other collections of his poetry. In 1480 he made a journey to Kyushu (recorded in his *Tsukushi no Michi no Ki*, Tsukushi being a poetic old name for Kyushu), not as a wandering priest in the traditional manner but as a celebrity, feted everywhere by his admirers.

Sōgi's reputation derives mainly from two *renga* sequences, *Minase Sangin Hyakuin* (1486; see *Bibliography*) and *Yuyama Sangin Hyakuin* ("One Hundred Poems Composed by Three Poets at Yuyama"; 1491); in each of these, three poets, led by Sōgi, took turns at composing short stanzas ("links") to form a single poem with many shifts of mood and direction. This expression of a multiple stream of consciousness was especially congenial to Japanese during the 15th century, when isolation and loneliness were the rule and *renga* gatherings, in which even the common people participated, provided rare opportunities for intellectual and literary companionship. Sōgi left over 90 works including the *renga* anthology *Shinsen Tsukubashū* (1495), diaries, works of poetical criticism, and manuals.

See Kenneth Yasuda, *Minase sangin hyakuin: a Poem of One Hundred Links Composed by Three Poets at Minase*, Eng. trans. (1956); Donald Keene (ed.), *Anthology of Japanese Literature* (1955).
(DD. K.)

SOGNEFJORD, an inlet of the west coast of Norway, the country's longest and deepest fjord, penetrating 114 mi. (183 km.) eastward into the mainland and reaching 4,291 ft. (1,308 m.) in depth. Sognefest lies at the entrance, which is sheltered by the Solund Islands. For the first 50 mi. (80 km.) from the sea the flanking mountain walls are virtually unbroken; beyond this, deep, narrow, secondary fjords penetrate them: Fjaerlands-, Sogndals-, and Lusterfjord to the north, Årdalsfjord to the east, Laerdals- and Aurlandsfjord to the south, which extend north toward the Jostedalsbre and Jotunheimen and south to the Hallingskarvet. At each fjord-head lies a small delta laid down by the stream that issued from the retreating glacier which formed the fjord (*q.v.*). This flat land is usually the site of the principal settlement because elsewhere the ground rises steeply from the water's edge. Branching from the Aurlandsfjord is the Naerøyfjord with the Naerøydalen, a steep valley of great beauty, at its head leading to the Stalheim Pass. Høyanger and Årdal are sites of big aluminum plants. The Sognefjord district is rich in traditions from the Viking and pre-Viking ages. The first settlers in Iceland came from this district. (L. H. HG.)

SOGN OG FJORDANE, a *fylke* (county) of western Norway. Area 7,154 sq.mi. (18,530 sq.km.). Pop. (1960) 96,045. In the north the Nordfjord penetrates 56 mi. (90 km.) eastward and in the south the Sognefjord (*q.v.*) 114 mi. (183 km.) into mountainous regions. Between these fjords the district of Sunnfjord is indented by several short individual fjords. The Jostedalsbre, the largest icefield in Europe, extends northeast-southwest from the head of Nordfjord nearly to the middle part of Sognefjord. In the island-studded coastal district, the economy is based on fisheries with farming as a subsidiary occupation. On gentle slopes along the fjords and in the valleys beyond the fjord-heads agriculture predominates. Fine orchards are characteristic of the inner and dry fjord areas. The magnificent scenery of these districts attracts many tourists. Abundant hydroelectric power has given rise to aluminum and other electrometallurgical industries. (L. H. HG.)

SOHO, a district in the City of Westminster, London, Eng., bounded by Oxford Street (N), Charing Cross Road (E), Coventry Street (S), and Regent Street (W); Piccadilly Circus is at the southwestern corner. A plan of 1585 shows the area as fields which in 1643 just came within the fortifications of London hurriedly put up against the royalists; a fort stood near the northern end of the present Wardour Street. Gregory King surveyed the area for building and in 1681 built King's, later Soho, Square, the district soon becoming fashionable. Foreign tradesmen, especially French Huguenots, finding few opportunities in the City, settled in Soho. In 1700 there were about a dozen French churches near and in Soho, but by the early 20th century the French had been displaced by, among others, the Italians whose quarter was originally in Clerkenwell. Soho has many famous names linked with it, including G. J. Casanova, William Blake, who was born in Broad (now Broadwick) Street, and Karl Marx; William Hazlitt lies buried in St. Anne's Church gardens not far from the bankrupt Theodore, king of Corsica. Soho, no longer a community, is known chiefly for its continental restaurants and food shops; Berwick market is within its bounds, and clothing firms, film companies, and publishers, especially of music, are established there. The name (*So ho* in ratebooks of 1632) is an old hunting cry.

SOIGNIES (Flemish ZINNIK), a town in the province of Hainaut, Belgium, 10 mi. (16 km.) NE of Mons, dominated by the towers of the collegiate church (10th–13th centuries), one of the country's best-preserved Romanesque buildings. Pop. (1961) 10,874. There was a Roman castrum (fortress) at the site, and the town was said to have been founded in the 7th century by St. Vincent who built a monastery there. The Old Cemetery, with some 16th-century tombs, is now a public park and contains a Romanesque chapel which now houses an archaeological and lapidary museum. Carboniferous limestone quarries are worked nearby. A hollow-glass plant operates in the town.

SOIL. The rocks and minerals of the earth's surface were the starting materials from which soils originated. Exposure to the elements and volcanic and tectonic action has resulted in the disintegration of these rocks and minerals to give a more or less unconsolidated residue over the earth's surface which is called the regolith. Organisms grew in and on the regolith, and their partly decomposed carbonaceous compounds were added to the mineral mixture. Insoluble residues were left in place. Soluble compounds were moved towards the surface, in extremely dry areas, and down and possibly into drainage waters, in humid areas. When these processes were allowed to operate without further geologic mixing for long periods of time, the regolithic material differentiated into an orderly sequence of layers, or horizons. These chemically and biologically differentiated top layers of the regolith are the soil.

Soil science and the use of soils will be discussed under the following headings:

Additional information will be found under Land Reclamation; Irrigation; Rotation of Crops; Fertilizers and Manures; Liming.

I. SOIL ORIGIN AND DEVELOPMENT

The surface of the regolith seldom remains in the place where it was first formed; during its millions of years of existence it has been moved from place to place by wind, flowing water, or advancing glaciers. Soil is any part of the regolith that has been in one place for a sufficient length of time and has been acted upon by natural physical, chemical, and biotic forces of sufficient intensity to develop detectable surface and subsurface layers called soil horizons. Soil-horizon differentiation in the regolith involves the accumulation of organic materials in the shallower horizons and the movement of dissolved mineral materials from certain horizons into neighbouring horizons (*see* fig. 1).

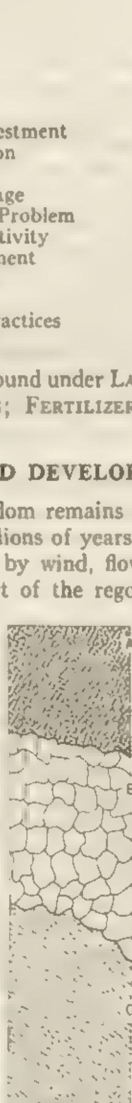

FIG. 1.—SCHEMATIC REPRESENTATION OF WEATHERING IN THE REGOLITH OF THE EARTH'S CRUST AND SUBSEQUENT SOIL-PROFILE DEVELOPMENT

The regolith was formed by the physical weathering or disintegration of massive rocks and minerals and by the chemical weathering or decomposition of some of the minerals in the parent rock. Rocks disintegrate or fracture into smaller and smaller particles due to alternate expansion and contraction resulting from heating and cooling, freezing and thawing, wetting and drying. Chemical weathering of rocks results from reactions of component minerals with oxygen and water and with carbonic, nitric, and sulfuric acids of atmospheric and biological origin.

Soils develop from the regolith by a continuation of physical, chemical, and biotic actions and reactions similar to those that originally formed the regolith and by a differentiation of the weathered regolithic material into a profile of horizons. For regolithic material to be classed as a soil, its surface must be differentiated from deeper material into from one to four possible master horizons designated from the surface downward as A, B, and C horizons and D layer. Master horizons are usually several inches thick (*see* fig. 2, 3 and 4). If minor differentiations occur within the master horizons, the subhorizons are designated by appropriate subscripts such as A_1, B_4, C_3, etc.

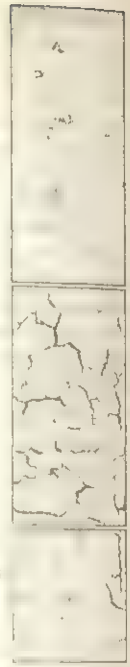

FIG. 2.—A TYPICAL SOIL PROFILE

Horizons become differentiated during soil development in the regolith because conditions vary with depth. In humid regions physical and chemical reactivity and biotic activity are much more intense in the surface than in subsurface materials. Dispersed and dissolved products are moved from the surface horizons to the subsurface horizons or they are leached completely from the developing soil profiles. In desert regions chemical and biotic soil-forming processes are much less intense than in humid regions, and the zone of greatest chemical and biotic activity is usually within one of the subsurface rather than surface horizons. There is seldom enough water in desert soils to move products of weathering from one horizon to a lower one. As a result of the above processes each horizon of a soil profile differs from the one above or below by one or more characteristics, such as colour, chemical composition, arrangement of individual particles, or size distribution of constituent particles.

The A horizons are the horizons of the surface layers of soil profiles. They contain more organic matter than the other horizons except in certain desert soils in which the production, preservation and accumulation of organic matter may be favoured somewhat more by conditions found lower down, in the B horizons. The A horizons are the most weathered and leached of the various horizons. In the soils of the cold humid temperate regions, weathering and leaching have left residues in the A horizons which are high in silica and low in iron and aluminum oxides and other sesquioxides (*see* also *The Chemical Properties of Soils* below). The opposite is true of the soils of the humid tropics in which soil-forming processes have left residues in the A horizons which are high in the sesquioxides and low in silica (*see* also Laterite).

The B horizons of the soils of the cold humid temperate regions may accumulate all or only part of the sesquioxides removed from the corresponding A horizons. In cases where only part of the sesquioxides has been deposited in the B horizons the remainder has been removed from the soil by drainage waters. Intermediate climates between the cold humid temperate regions and the humid tropical regions produce soils with A and B horizons having intermediate silica or sesquioxide residues and accumulations.

The humid temperate climates are conducive to the formation in the A and B horizons of a group of very finely divided hydrated iron and aluminum silicates called clay minerals. The B horizons of soils in these regions have been enriched by clay minerals carried by percolating water from the A horizons.

The C horizons of soils represent the types of material from which the A and B horizons were formed. These materials are

called the parent materials of the soils of which they are a part and their characters are determined by the rocks from which they were originally formed by weathering processes.

The D layers are beneath the soils and are not a part of the soil profiles. They are strata having properties much different from the overlying C horizons. They are strata, which, by virtue of their properties and shallow position, exert a significant influence on the properties of the soils above.

Some of the master horizons may be missing from soil profiles. The A horizons may have been removed from some soils by erosion. Other soils may be too young and too feebly developed to show B horizons. In still other soils C horizons may be absent because the original regolith was so shallow that it became completely occupied by the A and B horizons. In opposite cases where the regolith is extremely deep, D layers usually are not recognized because they do not influence the properties of the overlying soils.

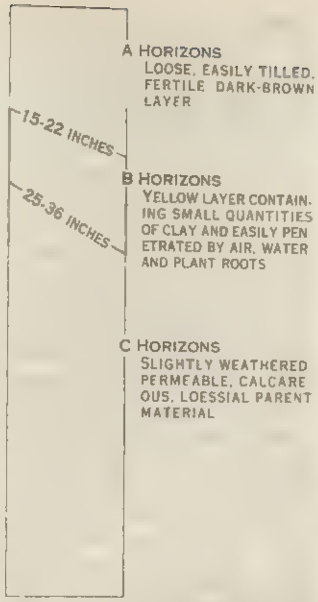

FIG. 3.—TYPICAL FEATURES OF PROFILES OF SOIL WITH HIGH PRODUCTIVE CAPACITY

Soils may also develop from thick layers of organic materials found in the bottoms of naturally or artificially drained swamps or lakes occurring in regions with cold temperate climates. These organic materials accumulated, before drainage, from dead water plants and other organisms. These organisms were only slightly decomposed due to relatively low temperatures and a lack of oxygen at the bottom of the swamps and lakes. After the organic sediments become exposed to air by drainage, they differentiate into horizons and develop into organic soils. The A horizons are first formed by partial oxidation of the organic compounds and slightly mineralized fractions are left as residues. As organic soils become older they become more and more mineralized to greater and greater depths.

The factors that influence the rate and kind of soil development include: the nature of parent material, climate, biological activity, topography or drainage, and the age of the developing soil profile. These factors, through combinations of many intensities, provide many environments and many possible variations in rate and kind of soil development. This can be illustrated by studies made on soils developed from regolithic materials deposited approximately 2,000, 10,000, and 200,000 years ago, respectively. The 2,000-year-old deposits are Indian mounds and the other two are continental glacial deposits, all occurring in humid temperate regions. The 2,000-year-old deposits show little if any soil-profile development; the intermediate regolithic materials have developed weak soil profiles; and the 200,000-year-old deposits have developed well-defined soil profiles. In contrast to this slow development in the temperate climates, in the tropics it is possible to find 50-year-old deposits of regolithic materials that have developed perceptible soil horizons.

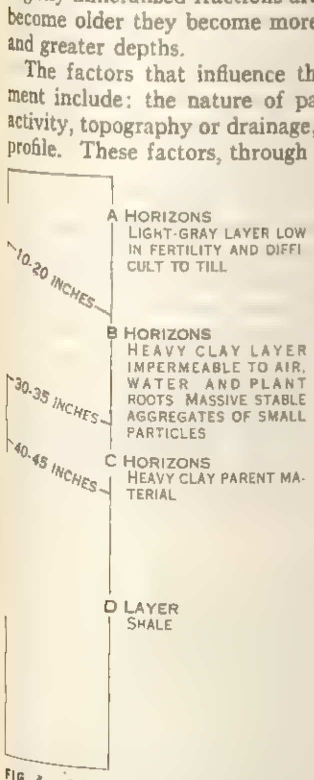

FIG. 4.—TYPICAL FEATURES OF PROFILES OF SOIL WITH LOW PRODUCTIVE CAPACITY

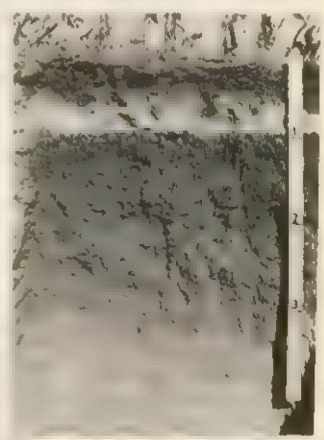
Variations in age, parent material, and environment have been responsible for the development of many kinds of soils on the earth's surface with many different physical, chemical, and biological properties and with wide ranges in productive capacities. These soil characteristics have been influential in determining the kind of native vegetation best able to survive in various parts of the world. They are also influential in determining the methods man must adopt in using and managing soils for crop production.

For more detailed discussion of the geologic processes involved in soil development *see* GEOCHEMISTRY; GEOLOGY: *Physical Geology;* HYDROLOGY; SEDIMENTARY ROCKS. (J. E. GG.)

II. SOIL CLASSIFICATION

Although soil covers the land as an almost continuous blanket, it differs greatly in character and in usefulness to man from region to region, from farm to farm, and even within single fields. Soil scientists, engineers, geologists, farmers, and others have named and classified different kinds of soil, each group according to its special knowledge and interest.

The early attempts to classify soil were based on its products rather than on its intrinsic properties, because men were interested in the fruits of the soil, not in the soil itself. Even educated people of the 18th and 19th centuries associated the soil with the lowly position held by those who tilled it, and few found it worthy of study. The infant study of geology was a reputable subject for scientists of those times, however, and European geologists were the first to make serious attempts to classify soil. To the geologists, however, the soil was merely a kind of disintegrated rock, and they classified it accordingly. This was the principal concept expressed in soil classification throughout most of Europe and the U.S. and Canada from about 1850 to 1920. Terms like granite soils, transported soils, and residual soils came from classifications by geologists.



BY COURTESY OF SOIL CONSERVATION SERVICE OF THE U.S. DEPARTMENT OF AGRICULTURE

FIG. 5.—A VERTICAL SECTION THROUGH A CLAYPAN SOIL SHOWING THE LAYERS DEVELOPED DURING SOIL FORMATION (SCALE IN FEET)

1. Development of Soil Science.—While soil classification was dominated by geologic concepts throughout most of Europe, a group of Russian scientists led by V. V. Dokuchaiev began to study the soil itself, not as decomposed rock but as a natural substance warranting special attention. They found that different kinds of soil had distinctive layers or horizons, and that the kind and arrangement of these horizons at a given place were determined by climate, vegetation, topography, and age as well as geologic material. Using this concept of dynamic soil formation, Dokuchaiev proposed the first classification of soil as an independent natural body in 1886.

The language barrier between Russia and the rest of the world prevented dissemination of the Russian concept of soil for many years. *The Great Soil Groups of the World and Their Development* (1908), by Konstantin Dimitrievich Glinka (*q.v.*) of the Leningrad Agricultural Institute, was translated into German in 1914 and, 13 years later, in 1927, into English. This work, when it finally became known, revolutionized soil classification throughout the world. Under its influence, European soil scientists emphasized concepts of soil development in their classification systems. The system of A. A. J. de Sigmond, published in 1933, was based largely on selected chemical properties acquired during soil formation. That of W. L. Kubiena, published in 1950 as *Diagnostics and Systematics of the Soils of Europe,* depended mainly on theories of the changes that occur in soils with time under different conditions. Most of the best-known studies dealt with the major genetic kinds of soil of large areas and little with the details of soil properties important within farmers' fields.

In the United States, as in Europe, the concepts of geology dominated soil classification until the Russian work became known. From 1860 to 1900, E. W. Hilgard developed a concept of soil similar to that of Russian scientists and published an accurate picture of soil properties, correlated with types of vegetation, later to become major bases of soil classification. Few understood Hilgard's concepts, however, and much of his knowledge went unnoticed.

The first major lasting contribution to soil classification in the United States came through the establishment of the soil survey in 1899. This work involved making maps on which areas of the different kinds of soils of farmers' fields were shown for predicting crop adaptation, productivity, and land values. Different kinds of soils, called soil series, were named after places where they were first found, such as Norfolk (Va.) and Hagerstown (Md.). Each series was divided on the basis of texture into units called soil types, which became the basic units of soil classification for practical application to the problems of fields and farms. Thus while the genetic kinds of soil of extensive regions were being classified as great soil groups in Russia, the soils of small areas important to the individual farmer were being classified as soil types and series in the United States.

2. Systems of Classification.—After the German edition of Glinka's work was published in 1914, C. F. Marbut, chief of the Division of Soil Survey of the United States, who translated the work into English, combined the Russian concept of great soil groups with the U.S. concept of soil types and series into a single system of classification useful for describing and naming soils of both extensive areas and individual fields. Marbut's system was presented to the First International Congress of Soil Science in 1927 and received worldwide recognition.

Knowledge about soils increased rapidly after 1930, and many schemes for classifying soils were proposed in different countries. In spite of modification of Marbut's system in 1938 and again in 1949, the soil survey staff of the United States Department of Agriculture under the leadership of C. E. Kellogg concluded that a completely new system was required to incorporate new knowledge and to eliminate the confusion of names and poorly defined classes that had developed. In 1952 the soil survey staff began the first of seven trial systems, each of which was circulated among leading soil scientists throughout the world for trial under their conditions and was revised to accommodate their findings. Linguists developed a terminology based on Latin and Greek and translatable directly into related languages. The seventh approximation was a system based on measurable soil properties rather than on theories of soil formation, although characteristics used to distinguish different kinds of soils reflected major concepts of soil development. The system was presented at the Sixth International Congress of Soil Science in 1960 in tentative form. It was adopted as the official system of the National Cooperative Soil Survey of the United States in January 1965.

In addition to the taxonomic classification of soil, mapping units of soil surveys were grouped in many ways to show such interpretations as crop adaptation, single properties, productivity, erosion hazard, and need for fertilizer or lime. The land capability system of the United States Soil Conservation Service, designed as a guide for planning use and management of farmers' soils, was one of the best known of many such interpretive groupings. Comparable but less-known groupings were developed for such special purposes as irrigation, drainage, and land appraisal.

The units of classification and mapping of detailed soil surveys have also been interpreted for engineering uses. In addition, engineers developed independent systems of classifying soil material according to texture and other properties important in engineering construction. Some confusion of names resulted because the engineering soil classifications deal mainly with soil as a material for construction (*see* SOIL MECHANICS), while those of soil scientists deal with it as a substance formed by natural processes.

(M. G. C.)

3. Soil Survey.—The purpose of a soil survey is to provide an inventory of the soil resources of a given area. First, the soils must be classified. This is done by making a field study at numerous locations of the surface and subsurface layers, samples of each being sent to the laboratory for physical and chemical examination. Next, a map is prepared showing the districts covered by the soil groups recognized. Finally, a written report is prepared giving general information about the area, descriptions of the soils, and suggestions for their use and management. Since 1935, soil surveyors have used aerial photographs in making soil maps.

In the United States, where soil surveys were begun by M. Whitney of the Department of Agriculture in 1899, the Soil Conservation Service of that department includes among its tasks responsibility for the National Cooperative Soil Survey. This produces maps and reports in collaboration with the state agricultural experiment stations and other state and federal organizations. Most United States surveys follow county boundaries, and include not only soil descriptions but land-capability groupings, types of agriculture, climate, and other significant information. In Canada, the soil survey is led by the Soils Research Institute of the national Department of Agriculture in association with the Experimental Farms service and the universities.

Soil maps based on texture (sandy, clayey, loamy, etc.) were included in the agricultural surveys of Great Britain made in the early 19th century, and some similar information was given on the early Drift maps of the Geological Survey. Chemical and mechanical analyses were included in the surveys made about 1900 by C. M. Luxmore and T. B. Wood and also by Sir A. D. Hall and Sir E. J. Russell, who based their *Report on the Agriculture and Soils of Kent, Surrey and Sussex* (1911) on the geological origin of the soils. These methods have been very generally replaced by mapping based on the forms of profiles (profile morphology), pioneered by Dokuchaiev in Russia. Surveys in Great Britain were established in 1939 and placed under the aegis of the Agricultural Research Council, London, in 1946. A soil map of Europe based on profile morphology was published in 1937 for the International Society of Soil Science, the coordinator being H. Stremme (Danzig); it was revised in 1964 under the auspices of the Food and Agriculture Organization of the United Nations (FAO).

J. A. Prescott (Waite Agricultural Research Institute) made the first soil map of Australia in 1931; much detail has since been added. In Africa, attention is concentrated on agriculturally important land, information from aerial, ecological, and reconnaissance soil surveys being used to fill the intervening spaces. G Milne made the first soil map of East Africa in 1936.

Basic information from soil surveys is important in planning land use in developing countries, and is provided by such organizations as FAO (Rome) and the Ministry of Overseas Development (London).

III. SOIL TESTING AND ANALYSIS

In agriculture, relatively simple soil analyses, commonly referred to as soil tests, are used extensively to evaluate nutrient availability in soils from a particular field or an individual farm and to predict whether increases in crop yield or quality will result from applications of lime or fertilizer. The development of these simple tests occurred largely after 1930. Previous attempts to relate nutrient availability in soils to the total amount of a nutrient element present in the soil or to that present in the soil water were not successful. Only when testing procedures were developed to remove and measure certain readily available portions of the nutrient elements present could definite relationships between the soil-test results and plant availability of the nutrients be established.

Following World War II interest in soil testing increased rapidly. The United States, most of the European countries and many other countries developed or expanded soil-testing laboratories to analyze soil samples from farmers' fields and advise the farmers as to the lime and fertilizer practices best suited for their soil conditions. While the majority of the testing is done for field soils, some laboratories make special tests for soils used in greenhouses or for other special uses. Most soil-testing laboratories are operated by agricultural colleges or universities or by governmental agencies. However, commercial laboratories, especially in the United States, offer this service to farmers.

Individuals may buy small soil-testing kits to test their own soils although this procedure is not generally recommended by soil scientists.

The first step in soil testing is the collection of the sample in the field. If soil conditions in the field vary because of different types of soil or different previous treatments, each condition should be sampled separately. Usually 15 or more small samples from a uniform area are collected and thoroughly mixed to provide one representative sample.

In the laboratory different tests are made for different nutrient elements. The amount of lime that should be applied is usually estimated from the pH (a measure of the acidity) of the soil sample. While tests for phosphorus and potassium are made almost universally, the testing procedures used in different laboratories are extremely varied. Solutions of acids, bases or salts of various concentrations or mixtures of these reagents may be used to extract the phosphorus or potassium from the soil. Then the phosphorus or potassium in the extract is determined. Certain reagents may provide reliable tests of nutrient availability in some soils but not in others, so different reagents are used in different laboratories.

Chemical soil tests for nitrogen are less commonly used. Most of the nitrogen used by plants is made available by microbiological decomposition of organic matter. Tests to measure the rate at which nitrogen is released from the organic matter have been developed but have not been widely adopted. Some laboratories test for calcium and magnesium in soil extracts similar to those used for potassium. Many soils contain soluble salts in amounts that are detrimental to plants. Most laboratories test for soluble salts by measuring the electrical conductivity of a soil-water suspension or of a water extract of the soil.

The boron removed in hot-water extracts of soil samples is determined in some laboratories in areas where boron deficiencies occur. Adequate soil tests for most other minor elements, such as manganese, copper, zinc, molybdenum, iron, etc., have not been developed or used extensively.

For advising farmers on the use of lime and fertilizer, the soil-test results must be interpreted differently for different crops, soils, and environmental conditions. Laboratory tests can provide only a relative measure of nutrient availability in the sample that is tested, not the actual amount of a nutrient element that will be available to plants during a growing season. Furthermore, different plants have different nutrient requirements. Various environmental conditions and soil properties influence nutrient availability to plants growing in a field, but do not influence the soil-test results. Because of this, the soil-test results must be interpreted differently for these different conditions. The interpretation must be based upon relationships developed between the soil-test results and the results obtained in fertilizer experiments conducted in the field under each of the different conditions.

Where adequate relationships have been developed, soil tests are useful guides in advising farmers on the use of lime and fertilizer. Much research is continually devoted to the development of better testing methods and to improving the relationships between the laboratory and field results for various soils and crops.

(Jn. J. H.)

IV. PHYSICAL NATURE AND PROPERTIES OF SOILS

The soil, in its relation to plants, provides a medium for root development and supplies nutrients for plant growth. To a considerable extent, the ability of soils to perform these functions is dependent upon their physical character and condition, which have much to do in determining moisture, air, and temperature relationships. Hence, the physical make-up of soils, together with their resultant properties, exert a controlling influence on chemical reactions and biological processes.

1. Component Parts of Soils.—Soil materials in a solid state—soil minerals and organic matter—constitute the soil proper; liquid and gaseous components, namely water and air, in the interstices between the solid materials, fluctuate continually, and frequently with conditions independent of the soil. The organic fraction varies widely, but seldom exceeds five per cent by weight, except in soils formed largely from plant remains. Organic soils, however, are of secondary importance to mineral soils.

The mineral constituents are extremely variable in size, shape, and chemical composition. The size of particles is one of the most significant characteristics. Water absorption, air movement, rate of solution, and ease of tillage are but a few of the numerous things affected by particle size. By mechanical analysis, which separates the particles into size groups known as separates, a quantitative statement of soil texture, illustrated in Table I, can be obtained. Results of a mechanical analysis do not include either organic matter or particles larger than two millimetres.

Table I.—*Quantitative Statement of Texture by Mechanical Analysis*

Name of separate	Diameter limits (mm.)	Amount present (percent)
Very coarse sand	2.0 –1.0	2.3
Coarse sand	1.0 –0.5	6.7
Medium sand	0.5 –0.25	8.2
Fine sand	0.25–0.10	9.4
Very fine sand	0.10–0.05	12.5
Silt	0.05–0.002	44.8
Clay	Below 0.002	16.1

Each separate is characterized by definite physical properties, due chiefly to the size of the particles composing it. As the particles become smaller, their total surface area, hence their effectiveness in transmitting properties to soils, increases greatly. Particles less than 0.001 mm. in size, especially those making up the colloidal or gluelike portion of the clay, possess active internal as well as external surface, and therefore are much more reactive than the other clay and larger particles. Because of their cohesive nature, clay colloids play an important role in the arrangement of particles.

Every soil is a mixture of separates, hence the physical properties exhibited are determined by the proportions of separates present. A group of soils having the same range in particle size and physical properties based on texture constitute a soil class. Soils in which the properties of no one separate predominate belong in one class. This class, known as loam, contains more than 35% total silt and clay with less than 50% and 27% of silt and clay, respectively; the permissible amount of sand would be too low to exert a dominant influence on the physical properties exhibited. When the silt content exceeds 50% in a mixture with less than 27% of clay, the properties of silt predominate and the soil is classed as a silt loam. The transition from loam to silt loam, or between other soil classes, is not abrupt but gradual. Variation in properties of soils within a class is indicated by descriptive terms as light, friable, and sandy; or heavy, plastic, and clayey.

For practical purposes, soils of the common classes can be grouped as follows: coarse textured soils, the sands and sandy loams; medium textured, the loams and silt loams; fine textured, the clay loams and clays.

Even though mineral particles are the very foundation of soils, they always contain some organic matter; its accumulation is an integral part of soil development. Humus, the partially decayed organic matter accumulated in soils, is a dark-coloured, structureless material, highly colloidal in nature. Unlike colloidal clay, the organic or humus colloids are not very cohesive and plastic; in general they tend to make sandy soils more cohesive and clayey soils less plastic. The efficacy of organic matter in changing soil properties depends on the amount present and the textural make-up of the soil. Thus, in determining soil class, it is necessary to take cognizance of the influence of organic matter in modifying physical properties associated with the mineral particles.

2. Structure and Its Practical Significance.—Structure deals with the arrangement of soil particles which occur as individuals, as groups or aggregates, or as a mixture of the two. In coarse-textured soils, the particles exist and function largely as independent units, but in fine-textured soils different-sized particles are bound together with colloidal materials. The aggregate produced may be either a dense, continuous mass, exemplified by a clod, or an open, porous cluster typified by a granule. With greater pore space and effective surface, the granule represents the more

desirable structure. These aggregates also vary in size, shape, and stability. A composite of the single grain and aggregate structures occurs in medium-textured soils. These are neither too open and friable, nor too compact and plastic; their physical condition is generally favourable for plant growth, and is easily maintained.

Structural differences result from variations in the kind and amount of colloidal material present. In the absence of soil colloids, the single-grain arrangements predominate, while aggregate formations are never well developed. These colloidal materials, including various clay minerals, oxides and hydrates of iron and aluminum, together with soil humus, are the products of different chemical and biological processes involved in soil development. Factors and conditions influencing soil development naturally would affect not only the formation of colloids, but also their distribution and behaviour in soils. As a result, marked differences in the natural structure of soils have been developed. Structural differences of virgin soils, also of the undisturbed substrata in cultivated soils, are of great value in any scientific study and classification of soils; too, they are of practical significance because of their relation to drainage, aeration, root development, moisture retention, and soil erosion.

When farmed, many soils soon lose much of their original aggregate structure. This change occurs primarily in the surface layer due to more rapid organic matter depletion, together with excessive and often improper handling. But, unlike texture, structure can be and frequently is changed; in fact, the main purpose of most tillage operations is to improve structure. Any control over many of the properties of a soil is possibly only if its physical condition can be modified.

3. Porosity and the Weight of Soils.—Porosity means total pore space, the soil volume not occupied with solid materials, varying from 35% to 50% in dry soils. As texture becomes finer, the size of individual pore spaces decreases but total pore space increases. Any change in structure, or organic matter, also affects the size of pores and porosity. Both are reduced by compaction, often desirable in sandy soils. Porosity is increased in fine-textured soils by proper tillage and more organic matter because of their influence in developing a granular structure in silty and clayey soils.

When compared on an equal volume basis, mineral soils when dry weigh more than water; organic soils, however, weigh less. The numerical ratio between the weights of equal volumes of dry soil and water represents the bulk density (or volume weight) of the soil. This fluctuates chiefly with differences in porosity, but is influenced also by the particle density (or specific gravity) of the various constituents in different soils.

Particle density is also a comparison of the weights of equal volumes of dry soil and water, but differs from bulk density since the equal water volume is determined by displacement and represents soil volume without pore space. Particle density is practically a constant for most mineral soils, with values of 2.65 to 2.70. Dark-coloured soils often are lighter, due to more organic matter; organic soils have particle density values from 1.5 to 2.0, varying with their mineral content. In comparison with bulk density, particle density of soils is relatively less important. Bulk density usually ranges from 1.0 to 1.5 for fine-textured soils, and from 1.2 to 1.7 for coarse-textured soils. Changes in physical condition of the surface layer of soils under cultivation cause wide variation in bulk density. In all soils it naturally tends to increase with the deeper layers, especially the subsoil.

When the bulk density is known, the weight of dry soil per cubic foot, or per acre foot, or of any fractional part, can be computed readily. The average weight of dry soil per acre 6½ or 7 in. deep, often called the "plowed section," is commonly given as 2,000,000 lb. Sandy soils are somewhat heavier, while organic soils weigh only about 1,000,000 lb. per acre 7 in. deep. These weight figures, either the averages or those computed directly from the bulk density, are useful in calculating the amount of soil water, the supply of organic matter or the quantities of plant-food elements present.

4. Soil Moisture and Its Relation to Plants.—Soil moisture, as here discussed, is exclusive of the water in chemical combinations occurring in certain soil minerals and organic compounds. The relative position of moisture with reference to the soil particles means that it is attracted unequally by the particles and acted upon by different forces. In consequence, soil moisture shows marked differences in its movement and availability to plants.

When air-dry, a soil usually contains only hygroscopic moisture; that is, moisture which adheres to soil surfaces in very thin films, moves by diffusion and is unavailable to plants. Colloidal materials are chiefly responsible for hygroscopic capacity. Hence, the capacity is never great in sandy soils, which are usually deficient in organic matter and have a low clay content.

Moisture, in excess of hygroscopic capacity, is retained in soil against gravity through the combined forces of adhesion, cohesion, and surface tension. This moisture represents the capillary form. It exists as films around and wedges between particles; moves as a film due to surface tension; and is available to plants. The innermost portion of capillary moisture, however, is held so tenaciously as to preclude true film movement, or its use by plants. Thus the soil contains both hygroscopic and inner capillary moisture when permanent wilting of plants growing on that soil occurs.

Gravitational water, known also as free, excess, or surplus water, is extremely variable, but is, in general, regarded as the difference between precipitation and a soil's capacity to absorb and hold water. Its presence in soils, contingent upon adequate drainage and a water supply in excess of capillary capacity, causes a deficiency of soil air and free oxygen, resulting in conditions which are inimical for seed germination, root development, and other desirable soil processes. Ordinarily, gravitational water is more important as a reservoir to replenish useful capillary moisture than as a direct source of water to plants.

The ability of soils to hold capillary water is determined by their porosity and adsorptive power. As the particles become smaller, or the organic content higher, or the structure more granular, the capillary capacity increases, due chiefly to the influence of clay or humus colloids, and or of the fact that more effective surface is exposed. The moisture content of soils, at any particular time, represents the balance between additions and removals of water. Natural precipitation, the main source of soil water, is supplemented in certain areas by irrigation, and at times by water brought up from deeper soil layers by capillarity; however, this process is generally too slow to be of real significance in supplying the water needs of plants. Removals of water from soils result through evaporation at or near the soil surface, transpiration from plant surfaces, percolation downward due to influence of gravity, and surface runoff. Loss by runoff decreases the potential supply of soil water.

Since water is often the chief limiting factor, even in humid regions, for crop production, every effort should be made to increase and conserve the supply of available soil water. Cultural and tillage practices that increase water absorption reduce surface runoff; moreover, these same practices control weeds, thus eliminating useless transpiration. Evaporation losses may be reduced through the use of windbreaks, and of mulches which may consist of either a protective cover of straw, boards, plastic or other materials, or a layer of dry soil. The soil mulch, however, is effective in saving water only when the water table is within capillary reach of the surface; but under this condition, drainage to remove the excess water usually is more urgent than mulching to conserve water.

Of the soil water absorbed by plant roots, only a small fraction is retained by the plant; an enormous quantity is removed from it by transpiration. This varies widely with different plants and climatic conditions, and is controlled indirectly by securing efficient use of the water transpired. Control on many soils, therefore, may mean the use of fertilizers to meet some nutrient deficiency, or it may mean other practices such as drainage, liming or proper tillage to improve productivity. Thus the transpiration per unit of dry matter produced is decreased. (*See* also IRRIGATION.)

5. Soil Air and the Need for Aeration.—The pores in soils are occupied by air or water or both, the proportion of air to water decreasing rapidly as the particles become smaller. Differences in texture, structure, and organic matter affecting porosity of soils also influence their capacity to hold water. Any increase in soil water decreases the amount of soil air. Thus, in poorly drained soils, and to a lesser extent in fine-textured soils having a compact rather than a loose condition, a deficiency of air exists.

Soil air, like the atmospheric air, consists of a mixture of gases, but it contains considerably more carbon dioxide and slightly less oxygen than does atmospheric air. With the gradual, but continual, depletion of oxygen and accumulation of carbon dioxide due to chemical and biological activities in soils, the need for soil ventilation becomes more urgent.

Aeration, the process by which stagnant soil air is replaced with fresh air, occurs naturally as a result of changes in temperature, variations in barometric pressure, movement of soil water, and other processes. In practice, however, one of the chief controls over aeration is exerted by regulating soil-moisture conditions, particularly through drainage. Tillage may be used either to lessen or promote aeration since sandy soils, usually too well aerated, need to be compacted, whereas clayey soils, frequently too compact and often crusted over, should be stirred to facilitate aeration.

6. Soil Temperature: Its Importance and Control.—Seed germination, plant growth, and, in fact, all soil reactions proceed through a wide range in temperature but each has an optimum range where it is carried on most efficiently. Successful crop production is no less dependent upon proper soil temperature than upon suitable atmospheric temperatures.

Direct solar radiation is the chief source of heat to soils. Differences in texture, structure, and organic matter that determine the moisture capacity of soils influence their ability to absorb and transmit heat. Dry soils, due to air in pores, have higher resistance to heat transfer than moist soils. Water is a better heat conductor than air, hence as soil air is replaced by water as the contact between particles, conductivity is increased; additional water, however, would retard the rate.

Heat generally moves from the surface downward as atmospheric temperature increases and from lower soil layers upward as it decreases. Changes in soil temperature lag considerably behind and are much less variable than those for atmospheric temperatures. Daily fluctuations in soil temperature are much greater in summer than in winter.

Differences in temperature of soils for the same degree of latitude are caused by variations in colour, moisture content, vegetative cover, and direction of exposure. The relation of colour to heat absorption is well known; but darker colours in soils are due chiefly to organic matter, which increases the amount of soil water. Only when the surface becomes dry, would the dark-coloured soil likely be warmer than the light-coloured soil.

Dry soil has a low specific heat, only one-fifth that of water. The greater amount of heat needed to raise the temperature of water causes soil temperature to decrease as soil water increases. Thus, wet soils are cold and slow to warm up in the spring.

A bare, uncropped soil heats more rapidly, attaining a higher temperature in summer than a similar soil protected by vegetation. The vegetation acts as an insulator, reducing both absorption of heat and loss through radiation. When protected by vegetation, leaves, or snow, heat is retained better and the soil remains warmer during the winter. In the Northern Hemisphere soils with southern exposure, receiving more heat per unit area, have higher temperatures than those with northern exposure, provided other conditions are similar.

Control of soil temperature is a matter of soil-moisture control. Excess water must be removed, if possible, by drainage. This will reduce evaporation, thereby conserving heat, and lower specific heat thus decreasing the amount of heat necessary to raise the soil temperature.

7. Soil Colour and Its Significance.—Colour provides information as to the conditions of and forces active in soil development, and represents an invaluable aid in soil classification. Since different colours are indicative of variations in conditions which influence productivity, colour is used as an important indicator of the agricultural value of soils. This use, however, necessitates that colour throughout the entire vertical section of soil be observed and interpreted in terms of soil properties affecting crop production.

Soil colours are of three main sources: decomposed organic matter, certain iron compounds, and other soil minerals such as quartz, kaolin and mica. Soils low in organic matter with iron absent or unoxidized are coloured by soil minerals. Their colours are often dulled or concealed by organic matter or iron compounds, or both. Much of the humus, the most stable portion of the soil organic matter, is a dark-brown or black residue coating the mineral soil particles. Under conditions of poor drainage and limited aeration, the reduced forms of iron together with anaerobic decay of organic matter favour the development of gray and drab coloration in soils.

Without good drainage and aeration, the iron could not be oxidized, nor the hydrated iron oxides produced to give the red and yellow colours. Red- and yellow-coloured soils are invariably low in organic matter; but when these colours, due mainly to hematite and limonite, are mixed with black from humus various shades of brown result.

With few exceptions, soil colour involves mixtures and is concerned with tints and shades rather than pure colours, so that ordinary colour charts are of little or no value in determining colour in soils. For this purpose standard soil colour charts, specifically made to include the colour range encountered in soils, are generally used.

8. Soil Tilth and Tillage.—The physical condition of the soil when considered in its relation to plant growth is known as tilth; its development must necessarily consider the requirements of the crop to be grown. Soil tilth, therefore, is more inclusive than structure, although the arrangement of the individual or aggregate structure particles is the fundamental basis of tilth in soils. While the textural make-up of soils cannot be changed practically, it is feasible to modify, through tillage practices, the structural condition of the surface layer.

Tillage, including any operation that stirs, inverts, fines, aggregates, or firms the soil, is used not only to prepare a satisfactory seedbed but also to maintain optimum growth conditions throughout the season. While plowing is generally regarded as the basic tillage practice, many soils, especially those of coarse and medium texture, often can be prepared adequately by use of a disk harrow. Frequently much of the desirable aggregate structure in the finer-textured soils is destroyed by plowing too much, or when too wet. It is imperative to avoid all tillage practices on heavy, plastic soils when wet; otherwise the soil runs together and upon drying is in a cloddy condition, which may persist for several seasons. Volume changes which accompany moisture variations due to alternate wetting and drying break down the clods and tend to encourage the formation of granules; this effect is usually more pronounced in the presence of organic matter since it counterbalances the deleterious effect of an excessive amount of clay colloids on structure. The general lack of colloidal materials in coarse-textured soils prevents puddling, or even desirable aggregation, hence the possibilities of structural modifications are limited.

Cultivation, the intertillage given a crop, is used primarily to destroy weeds. This practice also modifies structure of the soil to the depth cultivated, thus affecting aeration, water absorption, and evaporation. Conservation of moisture due to the formation of a mulch is of secondary importance to that due to the control of weeds. Furthermore, when cropped, the top portion of the surface soil is more valuable as a feeding zone for plant roots than as a soil mulch. (D. C. W.)

V. CHEMICAL PROPERTIES OF SOILS

The upper portion of the earth's crust, to a depth of a few miles, has been estimated to consist, to the extent of about 99%, of 10 chemical elements. They are, in decreasing order of abundance, oxygen (about 46.6%), silicon (27.6%), aluminum (8.1%), iron (5.1%), calcium (3.6%), sodium (2.8%), potassium (2.6%),

magnesium (2.1%), titanium (0.6%), and phosphorus (0.12%). All of the remaining elements, some 85 that are found in soils, constitute less than 1% of the earth's crust. Oxygen, the most abundant element, makes up by volume over 90% of the rocks and minerals, mainly as oxides of silicon, SiO_2, and aluminum, Al_2O_3. The 10 elements mentioned above are often referred to as the macroelements while the others like boron, cobalt, copper, manganese, molybdenum, and zinc are considered microelements. The primary rocks and minerals formed during the cooling of the magma are dominantly composed of the macroelements as alumino- and ferro-silicates of magnesium, potassium, calcium, and sodium. The microelements are most often found as occluded materials, generally as oxides, within the igneous rock formations. Igneous rocks account for approximately 95% of the earth's crust. Sedimentary materials are responsible for the remaining 5%. (*See* also ELEMENTS, CHEMICAL; GEOCHEMISTRY; SEDIMENTARY ROCKS.)

In the weathering of rocks containing primary or unaltered silicates, hydrolysis plays a dominant role. In hydrolysis, or decomposition by the union with water, the bases are split off as soluble compounds, such as hydroxides, carbonates, and bicarbonates. These, in a humid climate, are carried downward and out of the soil by percolating water, unless stopped by other chemical reactions which change them to less soluble forms. The insoluble residue from this weathering of the primary silicates is modified into secondary silicates of aluminum and iron which contain lesser amounts, or in some cases none, of the strongly basic elements, calcium, magnesium, potassium, and sodium. These secondary silicates are the clay minerals of soils, the principal component of the clay portion.

In addition to the silicate clay minerals, there occur in the clay size-range simpler compounds, the hydrated oxides of silicon, aluminum, and iron, that have split off from the primary minerals in the course of weathering. Along with these changes, organic matter accumulates from partial decomposition of plant and animal materials, so that the chemical components of the soil may be grouped in a general way into organic substances and inorganic or mineral substances.

In the following discussion, the chemical characteristics of the surface soils of the humid and semihumid temperate regions will be considered. These are the regions that contain most of the earth's cropped land and that support most of the world's human population. A brief discussion will then follow, indicating variations in surface soil character in some other climatic regions.

1. Primary Minerals.—The mineral constituents of soils may be grouped on a basis of size of particles. Sand and coarser particles, together with the coarser part of the next finer grade, silt, are essentially primary minerals. The silt size is between 2 and 50 microns (μ) in diameter ($1\ \mu = \frac{1}{1{,}000}$ mm. or $\frac{1}{25{,}000}$ in.). Primary minerals are defined as those which have undergone no appreciable weathering change. In soils they include, among others the feldspars, the pyroxenes and amphiboles, the micas, and quartz. The silts also contain the simple oxides of the microelements, apatites, and carbonates if they are present.

The primary minerals generally account for approximately 70% of the soil mass although individual soils may vary widely in this respect. Most of these minerals are very resistant to weathering, or decomposition, undergoing profound chemical change only through geologic periods of time. The primary minerals and that portion of the soil materials classified as silts, or coarser, contribute little to the dynamics of soil chemistry.

2. Secondary, or Clay Minerals.—Below the silt size-range is the clay fraction ranging in size from 2 μ down. The clay portion for the most part is composed of complex aluminum and iron silicates derived from the weathering of rocks and primary silicate minerals. The secondary or clay minerals, particularly those below the 1 μ size-range, are colloidal in size and present an enormous surface area for any given mass. Their reactions, therefore, involve surface energy and surface properties. In soils the soluble, chemically active substances accumulate at, and usually react with, the surfaces of these particles resulting in a great intensification of chemical processes around these minerals. Soil chemistry is essentially colloid, or surface, chemistry, and is controlled and conditioned by the clay minerals.

The structure of the clay minerals determines to a large degree their reactions in soils. Their basic structure centers around two crystal structural groups: (1) the silicon tetrahedron, a symmetrical configuration where a silicon atom is equidistant from 4 oxygen, or hydroxyl, atoms; and (2) the aluminum octahedron, a symmetrical configuration where an aluminum atom is imbedded in, and equidistant from, 6 oxygen, or hydroxyl, atoms. Under certain conditions a trivalent aluminum atom may replace the tetravalent silicon in the tetrahedron. Similarly divalent magnesium or iron often replaces the trivalent aluminum in the octahedra. In some clay minerals the lattice, or repeating structural sheets that make up the crystal, is composed of 2 silicon tetrahedra layers joined together by an aluminum octrahedron layer. Such minerals are called 2:1 lattice minerals. In others the lattice is made up of one silicon tetrahedron layer and one aluminum octahedron layer. These are called 1:1 lattice minerals. When ion replacements occur in the lattices such as aluminum for silicon or magnesium and iron for aluminum, a positive charge deficit is created in the mineral's crystal structure. The clay minerals are, therefore, negatively charged and may be considered as solid polyvalent anions. Most clay surfaces will also have "spots" of positive charge due to broken chemical bonds. In effect, parts of the surface may act as anions while other, much smaller, parts may act as cations.

The most common clay minerals found in soils are montmorillonite, illite, kaolinite, vermiculite, and chlorite. Montmorillonite is a 2:1 lattice mineral whose successive lattice sheets are bonded with varying amounts of oriented water molecules. Soils containing this mineral tend to shrink and crack when dry and become slick and sticky when wet. Montmorillonite is the principal clay mineral found in "gumbo" soils. Illites are 2:1 lattice minerals whose lattice sheets are bonded with varying amounts of potassium. The mineral is essentially nonswelling and imparts excellent tilth to soils. Illites can absorb, or "fix," both potassium and ammonium ions in forms that plants cannot feed upon. Kaolinite is a 1:1 lattice type mineral, nonswelling, and imparts good tilth to the soil. It has the highest anion exchange capacity of all the clay minerals. Both vermiculite and chlorite are 2:1 lattice type minerals but differ in the way the lattice sheets are held together. While widely distributed in soils, they seldom dominate the other clay minerals.

3. Ion Exchange.—The soil property known as ion exchange resides chiefly in the clay minerals. Ions are atoms or atom clusters that bear an electric charge. Those with a positive charge are cations while the negatively charged ions are anions. Anions and cations tend to unite with each other forming chemical compounds known as salts. When a salt dissolves in water a portion dissociates, or separates, into the constituent ions. The sum of the positive ion charges always equals the sum of the negative charges. The clay minerals are essentially solid surfaces with many negative charges and only a few positive charges. These must be balanced by adsorbed ions of opposite charge and attached through ionic bonds to the clay surface. The adsorbed ions can be removed and replaced by other ions of similar charge giving rise to the phenomenon known as ion exchange. Since the clay minerals are highly negatively charged, the adsorption of cations, and cation exchange, dominate their behaviour. A cation exchange reaction may be illustrated as follows:

$$\text{Clay} = \text{Ca} + 2\,\text{KCl} \rightleftharpoons \text{Clay} \langle^{\text{K}}_{\text{K}} + \text{CaCl}_2$$

Adsorbed ions are not removed from the soil by pure water and are, as a consequence, protected in the soil against excessive loss in drainage waters through leaching. This fact is of great importance in the practical maintenance of soil fertility because large quantities of available plant nutrient ions are thus preserved in the soil. The cations, however, are easily and instantaneously replaced from the clay by other cations in the soil solution. Not all cations are retained, or adsorbed, by clays with equal force. In general, the smaller the ionic radii of the ion and the greater

its charge, the more strongly it is adsorbed by the soil. The tightness with which cations are held by the soil, in decreasing order, is as follows: hydrogen > calcium > magnesium > potassium > sodium. Their relative abundance in the exchangeable form in mature soils of the humid regions is usually in the same order. In general, the laws of mass action govern the distribution of cations between the clay surfaces and the soil solution.

The capacity of different clay colloids and the soil itself to adsorb and hold cations is a fairly definite quantitative value, usually expressed in milligram-equivalents per 100 grams of sample, abbreviated m.e. The cation exchange capacity of pure clays may range from 10 to 200 m.e., while that of soils will usually vary from about 2 to 40 m.e.

Anions like phosphate, borate and molybdate may be adsorbed on the clay surfaces where positive charge sites occur. Anion exchange capacity in soils is usually very small as compared to cation exchange capacity, and is extremely difficult to measure quantitatively. Anions like the nitrate, chloride and sulfate are not adsorbed at all by the clays and are easily leached from the soil. The loss of cations from a soil through leaching can occur only if the soil solution contains salts or acids or anions that are not adsorbed by the clay minerals.

4. Soil Reaction and Acidity.—Inasmuch as acid hydrogen cations, as well as metallic or basic cations, can be adsorbed by the clay minerals, it follows that a hydrogen saturated soil is acid. The degree of acidity depends mainly on the ratio of exchangeable hydrogen ions to basic ions held on the clay surfaces, and on the hydrated aluminum oxide, or aluminum hydroxide, gels in the soil, which have both slightly acidic and slightly basic properties. Soils in humid regions gradually become more acid whether under natural or cultivated conditions, because calcium and other cations are gradually replaced from the colloids and removed from the soil by leaching. The replacing ion is chiefly hydrogen of carbonic acid and other acids from decomposing soil organic matter. The intensity of soil acidity is expressed by the term pH followed by a numeral. (*See* Hydrogen Ions.) The pH value of soils varies with the degree of saturation of the exchange capacity with bases, in contradistinction to hydrogen. Thus the base saturation of neutral soils (pH 7) varies around 75%, the remaining 25% being hydrogen. Virgin soils, *i.e.*, those that have never been cultivated, in humid temperate regions range from about pH 4.8 (strongly acid) to slightly alkaline, approximately 8.3, the latter value representing equilibrium with solid calcium carbonate. In some arid soils higher pH values are encountered, the high alkalinity being due to soluble carbonates of the alkali metal, sodium (see *Alkali and Saline Soils* below).

Soil reaction is important agriculturally because crop plants, as well as others, vary widely in their requirements and tolerances to soil acidity. Alfalfa and many clovers require essentially neutral soils, having a minimum pH of 6.2 to 6.5. Cranberries, at the other extreme, prefer acid soils with pH values around 4. The acidity, or hydrogen, in acid soils is easily neutralized by applying limestone. Neutralization of the hydrogen occurs according to the following reaction: $Clay = H_2 + CaCO_3 \rightarrow Clay = Ca + H_2CO_3$. Since carbonic acid is not stable it decomposes, $H_2CO_3 \rightarrow H_2O + CO_2$, giving rise to water and carbon dioxide. The soil hydrogen is thus converted to water, a neutral product, and removed from the soil.

5. Organic Matter.—All soils on which vegetation has occurred will contain varying amounts of organic matter. It is formed from, and composed of, plant, animal, and microbial tissues and their decomposition products. The stable portion of organic matter, or that which has undergone decomposition to a stage where the original source material is indistinguishable, is called humus. Humus is composed of a series of highly reactive brown to black coloured substances, usually of high molecular weight and containing nitrogen. The dark colour in soils, which is often associated with high productivity, is usually due to their humus content. As much as $\frac{1}{3}$ to $\frac{1}{2}$ of the humus may be humic acid, an alkali-soluble, acid-insoluble material. The remaining material is made up of amino acids, 10–25%, carbohydrates, 10–30%, fats, waxes, and resins, 2–6%, and other miscellaneous organic products.

Humus is quite resistant to decomposition and decay in soils. Many of its organic constituents are polar, or charged, thus adding to the soils ion exchange properties, especially the cation exchange capacity. Humus reacts with divalent cations, especially Ca, Mg, Mn, and many of the microelements, to form chelated compounds and salts. It also reacts with the soil clay minerals and becomes adsorbed on the clay surfaces. Such compounds, along with the gels, gums, and certain polysaccharides formed during the first decomposition stages of fresh plant residues, form protective coatings around the clay particles. These organic coatings decrease the stickiness of the clay particles and cause them to form stable aggregates. This gives rise to soils with excellent structure, and physical characteristics conducive to easy tillage. Soil tilth and resistance to erosion are closely related to the amount of organic matter the soil contains.

Soil organic matter contains about 5% nitrogen, 1% phosphorus, and 0.5% sulfur. All of the nitrogen in surface soils, except for a very small amount of ammonium held as fixed nitrogen in the illitic clay minerals and small amounts of unadsorbed nitrates present in the soil solution, resides in the organic matter. Over 30 amino nitrogen compounds have been definitely identified in humus, of which aspartic acid, serine, threonine, glutamic acid, glycine, alanine, valine, lysine, and the leucines are probably the most important. The nitrogen originally came from the air, first becoming incorporated into leguminous plants through symbiotic microbial fixation and later becoming a part of the humus through legume decomposition. (*See* Nitrogen, Fixation of.) If no fertilizer, or synthetically fixed, nitrogen is added to a soil, its ability to supply nitrogen to growing crops depends largely on the quantity of legumes grown and the continued decomposition, and loss, of the original soil organic matter supply. Although as much as 50% of the total phosphorus in surface soils is organic, such as phytin, the year-to-year quantity released during decomposition is relatively unimportant as a source of phosphorus for crops. Much of the infertility and poor tilth in soils that have been cropped for ages may be associated with their lack of soil organic matter.

6. Plant-Nutrient Supplying Ability.—Plants require for normal growth and reproduction the elements carbon, oxygen, hydrogen, nitrogen, phosphorus, sulfur, potassium, calcium, and magnesium in variable but fairly large amounts. In addition, iron, manganese, zinc, copper, boron, and molybdenum are required in small amounts, and are designated as trace or micronutrients. For some crops sodium, chlorine, cobalt, and vanadium may be required.

With the exception of carbon, hydrogen, and oxygen, the bulk of the plant nutrients are absorbed through the root system. Most of the essential nutrients are absorbed by plants as simple cations with the exception of phosphorus as phosphate, nitrogen as nitrate, boron as borate, sulfur as sulfate, and molybdenum as molybdate which are absorbed as anions. The soil solution seldom contains any of these ions in amounts adequate for normal plant growth. The exchangeable form of the basic elements is the principal immediate source from which the nutrients in the soil solution are renewed as they are taken up by plants. The exchangeable form also can be absorbed by plants directly through physical contact between the root hairs and colloid particles, forming an interface at which the hydrogen on the root can be directly exchanged for a cation on the colloid. An analogous system exists for the uptake of adsorbed anions by plants.

The clay minerals contain basic elements, *i.e.*, potassium and magnesium, in their internal structure, in addition to those in the exchange form. Illite is such a clay mineral rich in potassium. These forms are the reserve from which the more available exchange forms are renewed in the soil, and their abundance is a measure of the durability of chemical fertility. An analogous situation may exist with regard to phosphates.

Chemical soil tests for the plant-available forms extract and measure the adsorbed (exchangeable) bases and anions as well as the water-soluble nutrients, and they also dissolve the less soluble forms which contribute significantly, though to a lessser degree, to plant growth. Specifically, the objective of soil testing is the

measure of the amounts of exchangeable potassium, calcium and magnesium, the amounts of adsorbed and also easily acid-soluble phosphates, and the amounts of the ammonium and nitrate forms of nitrogen. Close correlations between these forms and plant response to added nutrients have been established by chemical soil tests and fertilizer experiments.

Almost all soils that have been cropped without fertilizer use for 100 years or more will have become deficient in one or more of the plant nutrients. Nitrogen is deficient in all of the agriculturally important soils of the world. Phosphorus and potassium deficiencies are very common. Zinc, manganese, iron, and copper deficiencies are commonly associated with sands and alkaline soils, while boron and molybdenum deficiencies are usually associated with the older, highly weathered soils. Calcium and magnesium deficiencies, which sometimes occur in the humid and semihumid temperate regions, are less of a problem since the soils are acid and the deficiencies are automatically corrected in the required liming program. (*See* also FERTILIZERS AND MANURES.)

7. Soil Variations with Climatic Environment.—Very young soils reflect the character of the parent material, but as weathering and its effects proceed, soils tend increasingly to show the effects of the climatic environment while the resemblance to the parent material grows gradually weaker or disappears.

Up to this point the discussion has pertained principally to soils formed under humid and subhumid temperate climates. With decreasing rainfall chemical weathering becomes less intense, soluble bases released by weathering are not leached from the soil and consequently the soil reaction becomes more alkaline, and the amount of organic matter present decreases. The colloid clays are dominantly of the 2:1 lattice type with montmorillonite the most common. The chemical fertility of such soils is usually variable and often quite low. The lack of moisture limits crop yields; therefore, such soils respond very favorably to irrigation and fertilization, particularly with nitrogen.

As one passes to subtropical and tropical regions of high temperature and high rainfall with intensified weathering and leaching, the silicate minerals are more highly weathered and bases and silica are leached away. The resulting soils are known as oxisols. Kaolinite is the dominant mineral, along with oxides of iron and aluminum, in the clay fraction. These soils are low in cation exchange capacity, low in present and potential fertility, and usually low in organic matter. Since bacterial activity is high throughout the year organic matter, in the upland soils, is so rapidly destroyed that its content is usually low in spite of its rapid production by vigorous growth of vegetation. In the deltaic regions, where most of the population resides, the soils are medium to high in organic matter. When properly fertilized and well managed, these soils have a tremendous capacity for food production.

In the cool to cold humid zones where forest vegetation is mainly coniferous the typical spodosol, or podsol, soil is formed. Decaying pine needles on the forest floor produce a highly acid leaching solution which not only removes the basic ions excessively but also dissolves iron and leaches it downward, where, with some of the aluminum and dissolved organic matter, it is redeposited in a characteristic tight subsoil, or B horizon layer. The surface layer immediately above this deposition is bleached white and ashy, and is high in silica. Kaolin, a 1:1 lattice mineral, dominates the soil clays. These soils are leached of their plant nutrients and are initially low in productivity. With good management, liming, and high fertilizer applications they become quite productive. (S. W. ME.)

8. Alkali and Saline Soils.—The term alkali has been rather loosely applied to all soils containing sufficient amounts of soluble salts to cause injury to plant life. When correctly used, the term alkali soils refers only to those soils that have a high pH value caused by sodium ions absorbed by the clay particles, and to those that sometimes have considerable amounts of the alkaline salt, sodium carbonate. Reaction between water and the sodium-saturated clay liberates sodium and hydroxyl ions into the solution, making it alkaline. These soils were formerly called black alkali in the U.S.

Saline soils are those that contain less absorbed or exchangeable sodium and that are high in nonalkaline salts such as sodium chloride and sodium sulfate, or those that contain enough salts such as sodium chloride to maintain flocculation and repress hydrolysis of the clay portion of the soil which is itself the insoluble salt of a strong base and a weak acid. The term white alkali frequently has been used for these soils. Alkali and saline soils are widely distributed in the drier areas of the world. On soils where salts may be a problem a great deal of foodstuff is produced. In regions of low rainfall, salts accumulate where drainage is poor, their origin being caused by insufficiency of percolating moisture to wash out and carry away in the drainage the soluble salts present in the parent soil material or those that are formed by its weathering. They are frequently formed in localized areas by seepage water from higher elevations. Soil-forming materials reclaimed from the sea, as on the coast of the Netherlands, are also saline. The salts that most frequently predominate are the carbonates, chlorides and sulfates of sodium, magnesium and calcium, or mixtures of two or more of these salts.

The tolerance of the various species and varieties of plants to soluble salts in soils is very different. Among the more tolerant agricultural plants are sugar beets, garden beets, milo, Bermuda grass, Rhodes grass, alfalfa, cotton, tomatoes, and barley. The less tolerant ones include beans, field peas, red clover, vetch, oats, and peaches. It has been found that the presence of high concentrations of salts in the soil solution (the liquid portion of the soil in which the plant roots obtain nutrients) limits the intake of water by plant roots. Yields are reduced approximately in proportion to the osmotic pressure of the nutrient solution. Although definite limits cannot be set for the amount of soluble salts required to reduce the yield of plants, less than 0.2% of salts in a soil is usually not harmful to salt-tolerant crops; in an alkali soil, lower percentages are harmful because of more toxic effects of the ions present. Relatively large amounts of salts may be added to the soil in irrigation water. In order to maintain the "salt balance" as much salt must be removed in drainage water from the soil as is introduced in the irrigation water.

Many irrigation projects have failed because of salinization caused by lack of proper drainage facilities or failure to use enough water to move excess salts down and out of the soil profile. Others have failed because of the high percentage of sodium in the irrigation water.

The chemical reactions by which a normal soil, the exchange complex of which (essentially the fine or clay fraction) is saturated with calcium and magnesium ions, is converted to an alkaline soil are as follows: Ca-saturated soil + $2NaCl \rightarrow$ Na-saturated soil + $CaCl_2$. When the sodium-saturated soil is leached by water little happens to it until the excess of soluble salts is removed. Further leaching brings about the reaction that is involved in the formation of the alkali soils of columnar structure called solonetz. This reaction is Na-saturated soil + H_2O = H soil + NaOH. Then, in the presence of carbon dioxide of the soil air the salt sodium carbonate is formed—$2NaOH + CO_2 + H_2O = Na_2CO_3 + 2H_2O$. Alkali soils are sticky, impervious to water, and unfavourable for agriculture. At the high pH values of alkali soils, dissolved organic matter coats the soil grains and gives a black colour. The reclamation of alkali soils is the reverse of the above processes. A soluble calcium salt such as gypsum is applied to the soil—2Na-saturated soil + $CaSO_4$ = Ca-saturated soil + Na_2SO_4. The sodium salt is then removed in the drainage water. Sulfur may be used in place of gypsum if the soil contains calcium carbonate. By biological action sulfur is converted to sulfuric acid, which reacts with the calcium carbonate to give gypsum. Good drainage is necessary to remove end products so that the reactions can proceed. Sodium-saturated colloids, in the absence of flocculating salts, "run together" or "freeze up." Sodium-saturated colloids in the presence of excess sodium salts may not be high in pH and are flocculated. *See* also IRRIGATION; LAND RECLAMATION. (L. T. A.)

VI. SOIL MICROBIOLOGY

The soil is not a dead, inert material; it is full of life, for a thimbleful of soil contains billions of living microorganisms. The

organic matter already present in the soil, as well as that constantly being added by higher plants, animals, and microorganisms, serves as a direct source of carbon and energy for the heterotrophic soil organisms; that is, microorganisms that derive their carbon and energy from organic materials. Indirectly, organic matter serves as food material for autotrophic bacteria—organisms that obtain their carbon supply from the carbon dioxide in the soil air and their energy from the oxidation of simple chemical substances.

Bacteria, fungi, actinomycetes (a filamentous form, including *Streptomyces*), algae, and protozoa—which have received the most attention from soil microbiologists—have a marked effect upon the productivity of soils. In general, highly productive soils contain an abundance of microorganisms, whereas less productive soils support a small population. While these facts do not prove that soils are productive because of their high microorganic population, or vice versa, there is much experimental evidence to show that microorganisms contribute to the productivity of soils through their varied activities.

1. **Decomposition of Organic Matter.**—One of the functions of soil microorganisms is the decomposition of organic matter added to the soil through the use of green manures—crops grown for soil-improvement purposes—animal manures, crop residues such as roots and stubble, and microorganisms. The sugars, starches, cellulose, and similar compounds in these organic materials serve as a source of energy for bacteria, fungi, and actinomycetes, and largely disappear into the soil air in the form of carbon dioxide. Other compounds more resistant to decay remain in the soil longer and are important contributors to the humus in the soil. Bacteria, fungi, and actinomycetes need nitrogen for their growth during the process of decomposition. Where the organic materials are low in nitrogen, microorganisms use the ammonium and nitrate nitrogen in the soil. Consequently, they may compete with grain crops for useful nitrogen where low-nitrogen organic materials are plowed under, resulting in a lower immediate yield than would be obtained in the absence of added organic material. Nitrate nitrogen is often lost in drainage water because of its high solubility. Such losses may be decreased by the use of low-nitrogen organic material on land having a high nitrate-supplying power during extended periods when no crops are grown.

Both farmers and city people, when preparing artificial manure, have taken advantage of the ability of microorganisms to decompose organic substances. In this process, leaves, lawn clippings, garden refuse, and similar organic materials are mixed with ammonium sulfate or nitrate, superphosphate, and crushed limestone. Microorganisms use the nitrogen in their growth processes; the limestone prevents the accumulation of acids; and the phosphate reinforces the manure. This process of making artificial manure is called composting. (*See* also FERTILIZERS AND MANURES.)

2. **Solution of Minerals.**—During the process of decomposition of organic materials, large amounts of carbon dioxide are produced. When dissolved in soil moisture, carbonic acid is formed and this weak acid may account for some solution of soil minerals. Some bacteria and fungi produce organic acids capable of dissolving minerals. Other microorganisms producing mineral acids are effective, to some extent at least, in releasing some of the nutrient elements from relatively insoluble soil minerals.

3. **Nitrogen-Fixing Bacteria.**—In the air above every acre of land there are about 69,000,000 lb. of elemental nitrogen. Curiously enough, most crop plants may be starving in this sea of nitrogen. Only when the nitrogen in the air is combined with other elements is it possible for crops to use this nitrogen in their growth processes. Similarly, most microorganisms need nitrogen that has been changed into organic or inorganic combinations.

Some bacteria are able to use the elemental form of nitrogen that exists in the air. Thus, they can grow in the absence of combined nitrogen and, at the same time, produce nitrogenous substances which may be used later by crop plants.

The legume-nodule bacteria (rhizobia) are examples of organisms that can use air nitrogen. They grow in association with leguminous crops and are responsible for the nodules or tubercles which are associated with most leguminous or pod-bearing crops, such as peas and beans.

Role of Legumes.—The nodule bacteria furnish nitrogen compounds for the leguminous plant, and the leguminous plant furnishes energy material for the bacteria. Such a relationship, in which dissimilar organisms live together for their mutual benefit, is known as symbiosis.

Because leguminous plants are able to use air nitrogen indirectly, they will grow well, if nodulated, on soils that do not contain enough useful nitrogen for maximum growth of a nonleguminous crop, such as corn. A plentiful supply of nutrient elements other than nitrogen is necessary, however.

The amount of nitrogen nodulated leguminous crops obtain from the air depends upon several soil conditions. Under favourable conditions, it is estimated that from 50 to 150 lb. of nitrogen per acre may be derived from the air. The amount of useful nitrogen in the soil, the kind of crops and the fertility of the soil (the relative amount of plant nutrients which are present) are factors affecting the amount of nitrogen that can be obtained from the soil.

The nodule bacteria vary also with respect to the amount of nitrogen they can take from the air. Some bacteria are highly efficient; other species have little capacity to obtain nitrogen from the air. Still others actually may be unable to secure air nitrogen and thus may be parasitic.

The supply of nitrogen in the soil may be replenished by growing nodulated leguminous crops if all or a part of the leguminous crops is returned to the soil. Obviously, the way the crop is handled determines the extent to which nitrogen-replenishment occurs.

No one kind of nodule bacteria will find a home on all leguminous crops. Of the approximately 10,000 species, only a relatively small number of leguminous crops and their nodule bacteria have been studied. These include about 20 kinds (strains) of nodule bacteria, recognized by their ability to produce nodules on different leguminous plants. There are some leguminous plants on which nodules never have been found.

Inoculation.—Because the success or failure of a crop may depend, in part, on the presence of nodule bacteria, farmers practise inoculation—the process of adding suitable nodule bacteria to the seed or soil—in order to be sure the leguminous crop will be nodulated. Where the leguminous crop is native to the area, inoculation is practised as a means of cheap insurance. Inoculation is very important for leguminous crops which are new to a locality.

Reliable commercial inoculants are sold by many seed stores. The information printed on the container gives the name of the crop or crops for which the inoculant should be used, as well as directions for its use. The cost per bushel of seed is comparatively low.

Other Bacteria.—In addition to the rhizobia, there are bacteria living independently in the soil; *i.e.*, they are free living and are capable of using air nitrogen in their growth processes. These bacteria are said to be nonsymbiotic. Some of the nonsymbiotic bacteria are aerobic, requiring free oxygen, while others are anaerobic, or able to live in the absence of free oxygen.

The *Azotobacter* are the most important among the aerobic nonsymbiotic nitrogen-fixing bacteria—those able to convert nitrogen from the air into nitrogen compounds. They are present in small numbers, rarely more than a few thousand in a spoonful of soil. However, the *Azotobacter* are found in most soils which are neither distinctly acid nor highly alkaline. Their importance in soil fertility is in doubt. Under highly favourable laboratory conditions, they fix appreciable amounts of nitrogen, but the evidence in natural soils is largely circumstantial. It has been estimated that the *Azotobacter* may fix from 15 to 40 lb. of nitrogen per acre per year.

Nitrogen fixation by free-living nitrogen-fixing bacteria may occur in poorly drained soils because several different microorganisms may live under anaerobic conditions and fix appreciable amounts of nitrogen. (*See* also NITROGEN, FIXATION OF.)

4. **Nitrogen Mineralization.**—Organic matter is the storehouse of nitrogen in the soil. The nitrogen fixed by both symbiotic and nonsymbiotic bacteria is present in the form of organic com-

pounds such as proteins and proteinlike substances. Before this nitrogen can be utilized by growing crops, it must be converted into inorganic forms. Some of the processes by which organic nitrogen is changed into inorganic forms are carried on by several kinds of microorganisms, but the final steps in the formation of nitrate nitrogen, the form most readily used by higher plants, are the result of the activity of highly specific organisms.

5. Ammonification.—Ammonification is the process by which ammonium is formed in soils from nitrogenous organic compounds. It results from the action of microorganisms. The majority of the soil bacteria, many fungi, and the actinomycetes decompose protein materials, utilizing the carbon for energy purposes and liberating ammonium produced in excess of the small quantities needed for growth of the microorganisms. Where large quantities of highly nitrogenous green manure crops are plowed under, correspondingly large amounts of ammonium are released. However, the ammonium that accumulates in most soils is transient, because it is utilized quickly by other microorganisms. Because of this quick utilization, it is not possible to measure directly the production of ammonium in soils, but accumulation at any specific time can be determined.

6. Nitrification.—Nitrification is the process of converting ammonium nitrogen to nitrate. When ammonium is oxidized, it is first changed to nitrite which, in turn, becomes nitrate upon further oxidation. Unlike ammonification, which is accomplished by numerous kinds of bacteria, fungi, and actinomycetes under both aerobic and anaerobic conditions, the change from ammonium to nitrite is achieved by the specialized bacterium, *Nitrosomonas*. Another specialized bacterium changes the nitrite into nitrate. Both of these bacteria are strictly autotrophic and aerobic. Their activity in the soil is restricted by acid conditions, consequently, they are most active in well-drained soils where acidity has been corrected by a liming program.

Nitrification varies directly with the temperature and moisture of the soil within certain well-defined limits. In a cold, wet spring, little nitrate is formed and the leaves of higher plants often are yellowish in colour, indicating a lack of nitrogen. As the temperature rises and the soil reaches an optimum moisture content, nitrification increases and the leaves of the plants become darker green, indicating a supply of useful nitrogen. Higher plants growing in low areas in fields are more apt to show nitrogen starvation in the early spring because of water and temperature relationships.

In any good soil-management program, the aim of the farmer is to make sure that conditions are favourable for nitrification at the time of year when nitrogen is used most heavily by the growing crop. Because nitrate nitrogen is subject to leaching, the removal of substances in water solution, it is undesirable to have nitrate accumulate when crops are not growing on the land. For example, ammonium is not leachable, but under favourable temperature conditions it is changed by nitrification into nitrate, which is leachable. Therefore, when farmers wish to plow under nitrogen fertilizers in the autumn, it is desirable to wait until the soil temperature is about 50° F or lower, to minimize the conversion of nonleachable ammonium into leachable nitrate.

7. Algae.—Soil algae occur in relatively small numbers in soils when compared with bacteria. Their numbers are in hundreds of thousands per gram of soil rather than in billions, as is the case with the bacteria. The algae contain chlorophyll—the green colouring matter in higher plants—and range in colour through greens, blue-greens, browns, and reds. The volume of individual cells is roughly 3 times that of bacteria and ⅓ that of protozoa. Typical water forms of algae are much larger.

The blue-green algae are able to fix nitrogen and may be agents contributing to the maintenance of crop yields on low-producing soils. Because algae are capable of getting their carbon from the carbon dioxide of the air and fixing their own nitrogen, they are credited with the formation of organic matter on volcanic ash and on burned-over areas.

8. Actinomycetes.—Actinomycetes are somewhat intermediate in size and shape between bacteria and fungi. In some respects they resemble both. They occur in smaller numbers than the bacteria, but are larger in size and frequently surpass the bacteria in weight per given unit. One of their main functions is the decomposition of organic materials. The characteristic odour of newly plowed soil is attributed to the activity of these organisms. Most actinomycetes are aerobic in nature and, like the fungi, are more abundant in dry than in wet soils. A few are parasitic on some plants and animals.

9. Fungi.—Fungi exist in soils in many different forms. Some may be seen only with a microscope, whereas others grow on the surface of the soil and have characteristic, visible shapes. Mushrooms are familiar examples.

The numbers and kinds of fungi present in soils depend upon moisture, temperature, the kind and amount of organic matter present, and the acid condition of the soil. Many fungi are active under conditions of acidity and temperature that many bacteria cannot tolerate. For this reason, certain groups, particularly the heat-tolerant organisms, are important in the decomposition of grain straw and strawy manure. Others are involved in the decomposition of nitrogenous organic materials with the liberation of ammonia.

Some fungi are capable of living in association with higher plants, particularly trees. They enter the roots of these trees, forming an association called mycorhiza (*q.v.*). They appear to benefit the host plant by increasing the capacity of the roots to absorb nutrients.

Microorganisms in general, but particularly fungi, are important agents in maintaining in soils a granular structure called aggregation. The threadlike network that they form tends to hold soil particles together in crumbs—a condition favourable for the absorption of water and for the exchange of air between the soil and the atmosphere.

Neither the enumeration of the kinds nor a description of the characteristics and activities of individual groups gives a complete picture of the importance of microorganisms in the soil. Except under very unusual and highly unfavourable conditions there is a continuous cycle of changes. Complex substances are broken down into simpler materials by some microorganisms, while the simple materials are combined to form more complex substances by other organisms. At any given time the status of the microbial population and its products are a result of the interaction of many groups of microorganisms. For instance, one-half of the phosphorus may be present in the organic fraction of the soil and the other half in the inorganic form. Microorganisms decompose a part of the soil's organic matter and change the phosphorus to an inorganic form that is useful for higher plants. At the same time, other microorganisms use the inorganic phosphorus as food and incorporate it in their bodies as organic phosphorus. This organic phosphorus is not available for the growth of higher plants until it is changed again into the inorganic form. Thus, in assessing the activity of the soil microorganisms, a series of checks and balances must be considered. (O. H. S.)

VII. SOIL FAUNA

Many members of the animal kingdom are present in both cultivated and uncultivated soils. Some of the animals are found within the soil for their entire life cycle, occasionally coming to the surface for short periods, while others spend only some definite portion of their life span in this subterranean environment. The animal population of the soil consequently consists of both permanent and transient inhabitants.

The soil fauna is composed of a variety of animals ranging from microscopic protozoa to vertebrates such as moles and ground squirrels. The major group of significance, however, is the invertebrate population. The simplest forms of underground animal life are the single-celled protozoa; this group, although part of the fauna, is discussed elsewhere with other soil microorganisms (see *Soil Microbiology* above).

The group of invertebrates discussed here includes a variety of distinct types, some ubiquitous, others occurring only infrequently and in small numbers. The major animals include the flatworms, the nematodes, certain mollusks—especially the slugs and snails—the earthworms, wood lice, millipedes, centipedes, a variety of

arachnids, and a broad spectrum of insects. In addition, a few vertebrate species make their homes in the soil.

On the basis of their feeding habits, the soil residents may be divided into categories, depending upon whether they feed on decaying organic matter (saprophagous), on living plants (phytophagous), on other animals (predaceous), or upon animal excretory products (coprophagous). Those that attack cultivated plants are a great menace to agriculture; but others play a positive role by aerating the soil and in many other ways.

The abundance of invertebrates in soil is determined in large part by the supply of available nutrients and by certain physical characteristics of the environment. For their optimum development, good aeration and drainage are necessary. Moisture conditions are significant, and the fauna tends to be present in smaller numbers when moisture is inadequate. Temperature is another important environmental influence, with little animal activity occurring at low temperatures. The addition of organic materials increases the population of animals, and each of the major groups is more abundant in manured than in unmanured soil.

The number of invertebrates in soil varies widely according to the environment, but in fertile, well-aerated soils the population ranges from several million to several hundred million per acre, exclusive of the protozoa. Most abundant are insects, nematodes (roundworms or eelworms), earthworms, and millipedes. Although there are vast numbers of smaller animals, these are so small that they make up only a fraction of the total weight of the fauna. The larger invertebrates, such as the earthworms and the myriapods (millipedes, centipedes, etc.), therefore, make up the bulk of the total weight, sometimes up to 90%. The fauna contributes as much as several hundred pounds of animal tissue per acre.

The common soil nematodes are nonsegmented worms barely visible to the unaided eye. They are endowed with the capacity for active movement when in a liquid film. Many different types maintain a subterranean habitat, and the number of species is immense (*see* ROUNDWORM). Some are saprophytic, using organic materials and even microorganisms as food; others prey upon members of the soil fauna including other nematodes, while a very important group can attack and parasitize growing plants. Some of the plant parasites prey upon one or a few plants, but others seem to be nonselective.

Mollusks such as snails and slugs spend part of their life in soil, and many mollusks will leave only infrequently. They prefer a moist environment and are common in shady areas at the soil surface as well as under rocks and surface debris. Although they will sometimes attack plants, they tend to utilize decaying materials. The mollusks are never abundant but may be present in numbers up to about 50,000 per ac.

Since the classical studies of Darwin, soil scientists have appreciated the significance of the earthworm (*q.v.*). These segmented worms spend their entire life cycle in the soil, emerging only occasionally. They are unfavourably affected by desiccation, low temperatures, and poor drainage, and they are generally absent when the soil reaction is highly acid. They show a distinct preference for well-aerated and well-drained localities. An available supply of organic matter is important, and the earthworm population is highest in soils receiving barnyard manure and in pasture and forest soils. Earthworms can feed upon organic litter but have certain distinct preferences in their nutritional habits. When present, animal manures are used. Not only is the number greater in organically rich soils, but the worms themselves are larger. Under optimum conditions, their numbers range up to several million per acre with a large bulk of the entire animal weight as earthworm tissue—up to a hundred or more pounds per acre. As they burrow, the worms excavate channels that increase aeration, improve drainage, loosen the soil structure, and provide paths for plant roots. The casts left by the earthworms tend to promote soil crumb aggregation as well. Darwin estimated that earthworms bring about 20 tons of material per acre to the surface each year—an amount sufficient to cover a field to a depth of one-fifth inch.

There are three major arachnid representatives: mites, spiders, and ticks. The arachnids are usually free-living in nature, although some can be parasites on plants or higher animals. Their burrowing habits probably improve the structure, aeration, and water movement in the soil.

Only two myriapods are encountered in appreciable numbers, the millipedes and the centipedes. Of the two, the millipedes are the more numerous, and soils rich in earthworms usually support the growth of many myriapods, with the population in each acre extending into the millions. Certain myriapods can utilize organic matter and living plants for their growth, while others are predaceous. This group requires adequate moisture in the soil.

Many genera and species of insects are present, either in the adult form or in the larval or pupal stage, and these are frequently the most abundant of the invertebrate animals in the soil. Among the more common insects are ants, springtails, termites, and beetle and fly larvae. Insects may feed upon subterranean portions of plants or may live saprophytically, while certain species lead a predatory existence. The plant parasites of this group pose a serious threat to agriculture.

Certain vertebrates burrow underground and spend part of their lives under the surface. Prairie, forest, and desert have their characteristic, burrowing species. Among the mammals are the moles, ground squirrels, mice, hares, shrews, woodchucks, badgers, and gophers; among the reptiles are snakes, lizards, and some turtles. The rodents in particular can be quite active in their movements through the soil.

The soil fauna has a great significance in soil structure and fertility and in plant pathology. The invertebrates are capable of causing a number of injuries to plants as well as being parasitic. There is evidence that the fauna may play an appreciable role in promoting the decay of organic matter, particularly in forest areas, although its significance is secondary to that of the microflora. As the animals burrow through the soil, they leave behind openings that improve aeration and drainage, although they may damage a cultivated field or wreak havoc on a well-tended lawn.

The fauna also can move a considerable quantity of plant residues as well as large numbers of microorganisms for considerable distances. The animal population serves to mix surface plant debris and forest litter with the underlying soil and also to move soil upward and leave it in the form of mound. In all respects, the soil fauna provides an interesting area of study for the soil scientist, the zoologist, and the plant pathologist. (M. AR.)

VIII. SOIL PRODUCTIVITY

Soil productivity is the capacity of a soil, in its natural climatic environment, to produce a specified plant or sequence of plants under a specified system of management. In their natural state, soils differ widely in productivity because of differences in their ages and in the materials from which they are formed. Most silt loam soils, for example, are naturally more productive than sandy soils, and mature soils are more productive than soils that are either young, geologically speaking, or very old. The productivity of a soil is also partly determined by the way it has been managed in cultivation. In discussing soil productivity, it is appropriate to do so in terms of its relation to management.

1. Soil Management.—Management can be defined as the combination of tillage, cropping, and soil-treatment practices used to produce a crop. The three practices compete with and complement each other. Desirable combinations of the three tend to eliminate the unfavourable effects on the soil of crop production, to reduce the adverse effects of climatic, insect, and disease hazards, and to push crop yields toward their potential. Under continuing poor management (poor tillage, undesirable sequence or choice of crops, and little or no soil treatment) the productivity tends to be lower and to vary widely. Under complete and balanced management, on the other hand, a soil can maintain or even improve its productivity, and consequently grow crops more economically. Good management increases the efficiency of the soil in meeting crop requirements and protects the soil from the deteriorating influences of crop removals, and from excessive drainage and erosion. (*See* also *Soil Erosion and Conservation* below.)

In practical agriculture there is a tendency to underuse and neglect cropping and soil-treatment practices, which leads to soil

exhaustion, greater susceptibility to hazards and declining productivity and lower economy of production. Field experiments with cropping systems and soil treatments dating from 1876 (Morrow Plots, University of Illinois) have shown a decline in yield of 60% by the second half of the 20th century for corn in continuous culture; the yield of corn declined at a slower rate when corn and oats were alternated; and the yield of corn remained constant when corn was rotated with oats and clover (*see* ROTATION OF CROPS). Under each cropping system, soil treatment (applications of manure, limestone, and phosphate; with a legume green-manure crop included in the corn-oats rotation) resulted in increased yields over the years.

Treatment practices are used to restore constituents that become deficient in the soil. The amount to apply depends upon the needs of the crop for soil-derived nutrient elements and the ability of the soil to fill these needs. Background information for planning these practices is obtained from chemical analyses of crop plants and from various tests for soil deficiencies. Chemical analyses of crop plants show that species differ widely in their requirements for nutrient elements and that the requirements for the different vegetative portions of a plant differ widely.

The data in Table II, giving the approximate quantities of five elements removed from the soil in moderate yields, show these relationships for some of the more commonly grown field crops. The legumes, such as alfalfa and soybeans, differ somewhat from the nonlegumes in that they can obtain from one-half to two-thirds of the nitrogen they need from the air if they are

TABLE II.—*Nutrient Elements in Field Crops*

Crop	Acre yields (cwt.)	Pounds in acre yields				
		Nitrogen (N)	Phosphorus (P)	Potassium (K)	Calcium (Ca)	Magnesium (Mg)

grown in association with the proper nitrogen-fixing organisms (see *Soil Microbiology* above).

Various tests for soil deficiencies can be used to indicate whether a particular soil can supply the requirements of crop plants. These include: (1) comparing crop yields and production practices for similar soils in the same community; (2) studying information that can be obtained from agricultural experiment stations; (3) watching crops during the growing season for symptoms revealing inadequate supplies of nutrient elements; (4) using chemical soil tests to detect deficiencies in available nutrients; and (5) using plant tissue tests to learn whether the plant is obtaining sufficient nutrients at various stages of growth.

In humid regions, low nutrient-supplying powers can usually be improved by returning deficient constituents to the soil. The constituents most likely to be deficient and the materials most commonly used to restore them are as follows:

Organic Matter.—Many cropping systems bring about the destruction and loss of soil organic matter. Crop yields tend to decline in proportion to the reductions taking place. The unfavourable effects of these losses can be offset by the regular return of fresh supplies. In field crop husbandry, this is done with animal manure, legume and nonlegume green manures and crop residues.

Nitrogen.—Organic matter is the source of soil-supported nitrogen. In some regions, as in the North American corn belt, the soil resources, the climatic conditions, and the type of farming followed make it possible to provide a high level of nitrogen supply, with animal manures and the residues of legume and nonlegume crops used in association with each other. It is often necessary to supplement the farm resources of nitrogen with commercial supplies. Even in the corn belt supplementary nitrogen is often needed, particularly if crop sequences are used that emphasize nonlegume crops and if little or no manure is returned to the soil. In some regions or under some conditions, it may be necessary to rely almost entirely on commercial nitrogen. Providing adequate supplies of nitrogen is a major problem in crop production.

Lime.—Lime affects soil productivity by modifying soil properties and supplying the nutrient elements, calcium and magnesium. Deficiencies are revealed by the development of soil acidity, to which most legume crops are especially sensitive. The proper use of lime, in the form of pulverized limestone, chalk, marl, or hydrated or burned lime, occupies a place of first importance on many soils.

Phosphates.—Phosphorus is supplied from both mineral and organic soil constituents. Deficiencies may be reduced or temporarily eliminated on some soils by utilizing subsoil supplies with deep-rooted legumes. Effective correction, however, is dependent on the use of phosphatic fertilizers such as superphosphate, basic slag, and rock phosphate. The economy of these carriers, which vary in chemical properties and behaviour, depends upon costs, soil conditions, and the type of farming followed. The need for phosphatic fertilizers is widespread.

Potash.—Crops acquire potassium from various potash minerals. Some soils are not abundantly supplied with these minerals. Other soils are well supplied with some of the less available forms, but are unable to provide some crops with sufficient quantities of potassium for good yields. Deficiencies in potassium-supplying power can be reduced by returning crop residues and animal manure to the soil; effective correction, however, is usually dependent upon the proper use of the potash fertilizers such as muriate of potash.

Minor (Trace) Elements.—In addition to the nutrient elements supplied in the above mentioned materials, crops also depend upon the soil for small quantities of manganese, sulfur, zinc, copper, boron, iron, and other elements. Deficiencies may be corrected by the direct application of suitable carriers or by the use of fertilizers containing the elements needed.

In correcting the nutrient-supplying deficiencies of soils, two general systems of practices have arisen: (1) the use of treatment materials in such ways as to improve the capacity of the soil for producing crops; and (2) the use of treatment materials in such ways, forms and rates as will favour the immediate response of specific crops in particular soil environments. The first system is directed toward the soil and involves a very careful planning of the cropping system and the incorporation, when needed of liberal quantities of crop residues, animal manures, lime, phosphates, and potash into the soil. The second system is directed toward the crop and involves the use of readily available nutrients, singly or in mixtures to provide sufficient quantities of nitrogen, phosphorus, and potassium for effective growth and yield.

In the United States, the interest in this system has led to the large-scale manufacture of fertilizer mixtures in the form of grades for specific conditions. Either system is effective when properly used, but the most favourable long-time economy in crop production is more likely to be attained when the essential features of both systems are properly combined.

2. Soil Treatment as an Investment.—On most soils the use of some soil-treatment system will increase the yields of crops more than enough to cover the additional costs of the treatment. As would be expected, poorer soils benefit more from soil treatment than do soils that are naturally highly productive. Soil treatment does not entirely close the gap between soils of different productivity, but it can effectively reduce the amount of variation.

The results of applying treatments to soils of different productivity are shown in Table III, where the benefits are indicated as reductions in acreages needed to produce the same amounts of crops. These reductions emphasize the importance of management systems that increase productivity, for if the same produc-

tion can result from less acreage, land is released that can be used to produce more crops or converted to other economic or social uses.

See FERTILIZERS AND MANURES; ROTATION OF CROPS.

(F. C. BR.)

IX. SOIL EROSION AND CONSERVATION

Soil erosion is usually described as the carrying away of soil by either wind or water. The Grand Canyon, the fiords of Norway, or the sinkholes and caves of the Karst region of the Balkan Peninsula are all examples of normal or geologic erosion, a slow process that occurs under natural conditions. Over long periods of time, usually thousands of years, it makes definite changes in the earth's surface. There is little man can do to change this process or the end result. For the mechanics of erosion *see* GEOLOGY. *See* also BREAKWATER; IRRIGATION; LAND RECLAMATION; RIVER; WIND EROSION AND DEPOSITION.

The erosion dealt with under this heading is less spectacular but much more vital to the welfare of mankind. It is the carrying away by wind or water of the soil from farms and ranches so necessary for the raising of food, fibre, and other agricultural products. Erosion of this type has been greatly speeded up by man's mismanagement of land, even to the point of destroying it for practical agricultural use within one generation.

1. Factors Affecting Erosion.—Chief among factors affecting water erosion is the amount of cover given the soil. Erosion is slow wherever soil is covered by trees or grass. At Zanesville, O., on comparable watersheds, woodland lost almost no soil during a nine-year period and pasture land very little, but cropland lost an inch of soil.

Closely allied to the matter of cover is the amount and intensity of the rainfall and its distribution during the season. Often a few hard rains which come at a time when crop cover is light will cause most of the soil loss. At La Crosse, Wis., four storms a year during a four-year period caused 95% of the total soil loss and 84% of the runoff from cornland.

Slope is another determining factor. The longer the slope the more soil and water are lost when cultivated. If the length of slope is doubled the soil loss is usually increased about 1.5 times. Similarly, steepness of slope affects the speed of runoff water and consequent soil loss. If the slope per cent is doubled the amount of loss is increased 2.5 times.

The nature of the soil affects the amount and seriousness of soil loss. The topsoil is generally the most valuable part of the soil profile because it contains more available plant food and organic matter. The surface soil can usually absorb water much faster than the subsoil. As the surface layer becomes thinner less water soaks into the soil and more runs off the surface, thus increasing the rate of soil loss. Losses from deep, open soils are less in amount and less serious than from shallow soils. The hazard increases for slowly permeable soils and those with tight, nearly impermeable subsoils.

The cropping system, kind and amount of tillage, and conservation measures used all influence the amount of erosion. Heavy cropping of a soil causes the organic matter to decompose rapidly. Tillage hastens the process. Reduction of organic matter causes a change in the structure of the soil. The granular condition or clumping of the soil particles into crumbs like grains in a popcorn ball is largely lost. The soil particles lose their tendency to stick together and are less able to resist the action of wind and water.

The main cause of wind erosion is lack of vegetative cover. This may be due to drought and high temperatures which reduce growth of vegetation; to tillage, and growing of cultivated crops that afford insufficient cover; and, in the case of pastures and ranges, to overgrazing. When soil is relatively bare, alternate freezing and thawing or wetting and drying loosens the surface soil and breaks down soil aggregates to granules that can easily be picked up by wind. The most critical seasons are late winter and early spring, when the wind usually blows strongest, the land has the least vegetation and soil is most susceptible to movement. Wind erosion is particularly serious in arid and semiarid regions.

2. Progressive Erosion Damage.—Soil erosion may be so gradual that serious damage is done before the land occupant is aware of what is happening. Each time a hard rain hits bare land, soil is torn loose and swept away. Each raindrop hits the bare earth like a tiny bomb, sending the wet soil in every direction. Not only is soil torn loose to be washed down the slope but available plant food is dissolved and carried away.

Soil damage occurs in successive stages. At first the principal loss is by sheet erosion; that is, each time it rains the runoff water will remove a thin layer of surface soil. As the surface soil becomes thinner small rills (miniature gullies) appear. On cropland these rills are erased by the next cultivation and the field looks much as before. After most of the surface soil is gone gullies may become the principal problem.

In gully erosion, channels are cut by water that has concentrated

BY COURTESY OF U.S. DEPARTMENT OF AGRICULTURE

FIG. 6.—SOIL EROSION

(Top left) A single drop of rain; (bottom left) the amount of soil it displaces as it hits the ground; (right) if unchecked, the combination of rain, runoff water, and wind quickly renders land unfit for cultivation or even for pasture

in the natural drainage ways or draws in a field. These channels may vary from a few inches to many feet in depth and up to many feet in width. As a result of gullying soil is lost, tile lines are washed out and fields are divided into two or more parts. Gully erosion is the most familiar type of erosion, doing serious injury to farm land. In the most advanced stages gullies may render land unfit for practical use for cultivated crops or even pasture. Reclamation of badly eroded land is expensive in any case, and full restoration is usually impossible except by natural processes of soil formation which require long periods of time. Sheet erosion, however, is actually more common and more serious than gully erosion because it takes place so gradually that the damage may not be recognized.

Soil damage by wind erosion is serious and extensive. Farmers in affected areas suffer crop damage or complete loss of crops. Serious as this may be, the greatest loss is that of the fine soil fractions (silt, clay, and organic matter). The wind exerts a sorting action on some soils much like a sieve. The finer particles, which contain the major part of the plant food elements, are gradually sorted out and carried away. Left behind is the coarser portion, which is less fertile and is often more erodible than the original soil.

Water and wind erosion result in much additional damage. Productive lowland soils often are covered with sand, gravel, stones, and low-fertility subsoil washed from slopes above. Water-borne silt fills stream channels, drainage ditches, and reservoirs, thus interfering with drainage and shortening the usefulness of lakes built for flood control, water supply, and recreation. Winds often cover productive land with infertile sand and bury railways, highways, fences, hedges, shelter belts, and even farm buildings.

3. Erosion as a Worldwide Problem.—Surveys made in different countries have shown that erosion has damaged or ruined for practical use hundreds of millions of acres of once-productive land all over the world. Induced erosion continues to be a major problem in every agricultural region in the world except in northwestern Europe. In Great Britain and other countries of northwest Europe, well-distributed rainfall, lack of torrential rains, and centuries of careful husbandry have preserved soil fertility remarkably well. During World War II, increase in the misuse of land changed this situation, however, and serious erosion in parts of the uplands of England, Scotland, and Wales resulted from up-and-down hill farming of potatoes and other row crops.

The erosion problem appears to be common throughout the world. This conclusion was borne out by the Food and Agriculture Organization of the United Nations (FAO) in a bulletin, *Soil Conservation, an International Study* (1948). After reviewing conditions in the United States and citing examples of serious and widespread erosion in China such as, "The Yellow River is the muddiest great river in the world," the report continued: "But these are only examples—the problems of soil conservation are world wide. They are particularly acute in India, where, as in China, there is tremendous pressure of population on natural resources even more meager; in the Mediterranean region of Europe and the Near East, where centuries of human occupation and the nature of the climate and land forms have favored rapid soil erosion; in Latin America, where many countries with dense populations have rapidly eroding lands; and in South Africa and Australia, where conditions and problems and the history of occupation are similar to those of parts of the United States of America." These conditions to a large extent still prevail.

In the United States a National Inventory of Soil and Water Conservation Needs, completed in 1961 under the direction of the U.S. Department of Agriculture, Soil Conservation Service, reported the amounts and usages of nonfederal rural land in the 48 mainland states as shown in Table IV.

The report revealed that nearly two-thirds of all nonfederal rural land needed conservation treatment of some kind and 8,323, or 65%, of the delineated small watersheds needed community-type projects for flood prevention and water management.

4. Conservation and Productivity.—In its simplest sense, soil conservation means the saving or preserving of the soil. This would be a relatively easy problem were it not that while saving

TABLE IV.—*Amounts and Usages of Nonfederal Rural Land in the U.S.*

Use	Acreage	Percent of tota.
Cropland . . . . Land currently tilled	447,399,000	31
Pasture and range. . . . . Land in grass or other long-term forage growth used primarily for grazing	484,716,000	33

Other land . . . . Farmsteads, farm roads, "idle" land, wildlife areas, etc.	66,271,000	5
Total	1,448,037,000	100

*Excluding Alaska and Hawaii.

the soil it is necessary to use it. Man must depend on it for most of his food and fibre. Soil conservation, therefore, involves saving the soil from erosion and improving its fertility and productivity while at the same time using it to grow needed products.

In addition to protecting and improving the land, soil conservation yields many side benefits. It helps lower the cost of farm production. This, in turn, increases farmers' profits and helps lower the cost of food and clothing to city dwellers. Soil conservation helps check drought damage in dry seasons and reduces flood crests in small and large streams in wet times. It reduces siltation of streams, reservoirs, and harbours, thus helping to insure a cleaner water supply for cities and towns, improve navigation and provide a better habitat for fish and other forms of wildlife. Soil and water conservation go hand in hand, for soil conservation is dependent on good water management. Conservation methods do away with the ugly scars of erosion, thus providing a more beautiful countryside in which to work or play.

5. The Conservation Movement.—Soil depletion and erosion began to take their toll early in the history of the American Colonies. Most of the early colonists came from areas where rains fall gently. Therefore they were not prepared to handle soil in the North American climate, where rain often falls with great intensity. They cut down the forests along the eastern coast, built their homes and planted corn and other crops in the cleared fields. More and more land was plowed to produce food for the increasing population and for production of tobacco and grain that could be traded abroad for needed commodities.

Then a few farmers in the older sections noticed a change in the soil. At first it had been dark, in some places almost black, but it gradually became lighter in colour. When a heavy rain came the loose soil mixed with the water and the muddy mixture flowed down the hills, carrying with it the richest portion of the soil—topsoil.

Destruction of soil by gullies and floods was noted by writers even before the Revolutionary War. By 1775 rivers that once ran clear were described as being black with mud. Early Massachusetts records indicate that most of the land near the coast was abandoned at least once before 1800.

Some of the leading men of that day were deeply concerned. Patrick Henry is credited with saying, "He is the greatest patriot who fills the most gullies." George Washington, who was an industrious farmer, was continually striving to conserve his land and check erosion. In his final message to Congress in 1796, he urged the creation of a board of agriculture, but it was not until Lincoln's administration in 1862 that the United States Department of Agriculture was created. Thomas Jefferson was constantly looking for ways to improve the productivity of his soil. While Jefferson was president his son-in-law, Thomas Mann Randolph introduced a system of horizontal plowing on his land that was the forerunner of contouring. The results delighted Jefferson. But people generally were not concerned about soil damage since there was so much virgin land. During the following century they moved west, clearing the forest for cropland, plowing the grasslands of the middle west and much of the Great Plains, and on to the Pacific coast.

Conservation sentiment was built up slowly. Early in the 20th century Pres. Theodore Roosevelt called the first conference of

governors to consider conservation of natural resources. Interest thus aroused led to the purchase of the first national forests and the establishment of the U.S. Forest Service.

Interest in soil conservation lagged during World War I and the agricultural depression of the 1920s. A soil surveyor in the Bureau of Soils, H. H. Bennett, was, during all this period, persistently calling attention to the serious erosion he had found in his survey work and trying to arouse interest in a corrective program. The movement took a big step forward in 1929 when Congress approved the establishment of soil conservation experiment stations to: (1) measure the rates of soil and water loss; (2) determine the extent and location of damage by erosion; and (3) develop methods for controlling erosion. Soon there were ten stations in operation gathering the information needed for an attack on the erosion problem.

In 1933 the Soil Erosion Service was set up in the Department of the Interior as one of the emergency agencies to help the country out of the economic depression of the early 1930s. Bennett was made chief of the first erosion control agency ever established by an important nation. In 1935, on the heels of the worst dust storm the U.S. had ever seen—dust from the Great Plains reached Washington, D.C., and drifted far out to sea—Congress passed Public Law 46, the first soil conservation act in the history of the United States or any other nation. The law established the Soil Conservation Service in the Department of Agriculture, replacing the Soil Erosion Service. The new agency was charged with carrying out, in cooperation with farmers, a program demonstrating good land use and erosion control. To facilitate the program, labour from the Civilian Conservation Corps (CCC) was made available. The work was carried out first on farms in project areas covering representative watersheds throughout the country, a watershed being that area of land which drains into a single stream, river or other drainageway. Later it was extended to farmer cooperators in CCC camp areas in each state. But all this was demonstration of limited scope. There was need for farmers and government to work together to apply the lessons to all farm and grazing lands.

Early in 1937 Pres. Franklin D. Roosevelt wrote to the governors of the states pointing out the need for state legislation to enable farmers to take necessary cooperative action in furthering the soil conservation program. With the letter was a proposed standard state soil conservation districts act that provided for the organization by farmers of soil conservation districts as governmental subdivisions of the state to carry on projects for erosion control.

The suggestion was well received. Arkansas became the first state to have a soil conservation law on its books. In Aug. 1937 the Brown Creek Soil Conservation District in North Carolina was organized as the first in the United States. By 1948 all states and territories had passed soil conservation district laws. In the second half of the 20th century approximately 3,000 districts had been formed to include the major part of the land in farms and ranches throughout the United States and its territories.

The U.S. Soil Conservation Service shifted its program to do most of its work in cooperation with these districts. The service assigns to each district one or more technicians to help farmers plan and apply conservation programs on their farms. The assistance includes: (1) a detailed soil survey of the farm or ranch; (2) a conservation plan drawn up by the farmer and technician working together; (3) application of practices called for in the plan; and (4) maintenance of the established practices. Any farmer may participate by agreeing with the district directors to conserve and use his land properly.

Many conservation practices can be applied by the farmer without assistance. But drainage, terraces, strip cropping, farm ponds, diversions, land smoothing, gully control structures, and the like require more technical skill than the farmer ordinarily has. The technical knowledge is supplied by technicians who work with the soil conservation district.

The U.S. Soil Conservation Service is extending its service to all users of land whether farm or nonfarm. The Food and Agriculture Act of 1962 assigned new tasks to the Soil Conservation Service in rural recreation, resource conservation and development projects, watershed development, and cropland conversion. Soil surveys are made for use in rural-urban planning and information on soil and water use is provided for urban fringe areas. Plans for watershed projects include recreation and wildlife development, water supply for municipal or other use as well as conservation of farmland and flood control.

The program of the soil conservation service has stressed work on a watershed basis. Early project areas were based on watersheds and the boundaries of many soil conservation districts are those of a watershed. In 1944 the service was authorized to apply special treatment for flood control on 11 watersheds in 12 states. In 1953 work was authorized and started on a pilot-watershed program covering 60 small watersheds in 34 states. In 1954 under the Watershed Protection and Flood Prevention Act (Public Law 566) the service was designated as the U.S. Department of Agriculture representative agency to cooperate with local organizations in small watersheds throughout the nation in work aimed at upstream watershed conservation and flood control. Response to this program was widespread in all states. In all of these watershed efforts the work is carried on in cooperation with local landowners.

Costs are shared by local organizations and the federal government. Amendments to Public Law 566 encouraged multiple use of watershed reservoirs. Recreation and water supply for municipal and industrial use are included in many of the small watershed projects.

Results following high intensity, flood producing storms in several well-developed watersheds in different parts of the country have been most encouraging. Upstream retarding dams used along with recommended soil and water conservation measures on the watershed lands have greatly reduced flooding, erosion and siltation.

In 1956 a Great Plains Conservation Program was authorized by Congress to help farmers and ranchers of the region develop long-term plans for their land, including soil and water conservation measures and the land-use adjustments needed to achieve a more stable agriculture. It provided technical aid and cost-sharing assistance over a contracted period of years to farmers and ranchers in designated counties for applying measures as part of an approved plan. The soil conservation service cooperates with local, county, state, and regional agencies and organizations to promote this program.

6. Methods of Conservation.—Appropriate use of the land depends upon land contour, type of soil, and climate. Land may be level, slightly or steeply sloping or even mountainous. Soil may be sandy or clayey, fertile or almost barren. Climate also varies. Therefore the farmer or rancher has a real problem in deciding how best to use his land, for there may be several kinds in his holdings. There are many examples of land that has been ruined or badly damaged because it was put to a use for which it was not fitted. To help a farmer or rancher with this problem, soil conservationists make a careful survey of the entire farm and put each area into one of eight broad classes of land-capability according to kind of soil, slope and degree of erosion. Each class is shown by a different colour or Roman numeral on the map of the holding. A farmer can refer to the map and quickly see whether a field can be safely cultivated or whether it should best be used for grazing, forestry or wildlife.

An important point in land management is to treat each acre according to its needs. After the best use for land is determined, the next problem is to treat each acre in such a way that it will produce as much as possible without injury from erosion. As stated above, good vegetative cover is the first defence against soil loss and runoff. Therefore, proper treatment of all classes of land will provide adequate cover.

For forest and woodland this involves protection from fire, managed cutting, and replanting if needed. For ranges and pastures approved practices include avoidance of overgrazing, resting to encourage growth of better pasture plants, renovating, fertilizing, and reseeding. The program varies widely from the pastures of humid regions to the ranges of arid and semiarid areas.

Cropland is used more intensively than other land on the farm.

More fertility is removed and cultivation encourages the breakdown of the organic matter which helps a soil resist erosion. The soil, when left bare, is open to the beating action of raindrops. This is especially true of row crops, such as corn, soybeans, cotton, and potatoes, which are cultivated for weed control. Special care must therefore be taken to maintain and improve fertility, add new organic matter, and protect the soil from erosion.

7. Minimum Tillage.—Working the soil less helps reduce the erosion loss from row crops. For years, in preparing a field for a crop of this type, it has been customary for farmers to work the soil into a fine seedbed by plowing and then going over the field several times with disk, harrow, or other tillage tool. Under the system called "minimum tillage" the aim is to use the least amount of tillage that will insure quick seed germination and satisfactory growth of the row crops. Minimum tillage saves one or more trips over a field, resulting in less expense for labour and for machine operation. In the minimum tillage system the seedbed is left with larger clods; more water sinks into the soil, less water flows down the slopes; consequently less soil is eroded from the field.

In the cropping system row crops are usually used in succession or rotation with small grains such as wheat, oats, barley or rye, and meadow crops—legumes or grasses or mixtures of the two. As protection against erosion, meadow crops are most effective, row crops the least and the small grains in between. How often each of the three classes of crops should be used in the rotation depends on the capability class of the land and the erosion-control practices employed (see *Soil Productivity* above). (*See* also ROTATION OF CROPS.)

8. Other Erosion Control Practices.—Even though good land use, a suitable crop rotation, and soil treatment are used, some additional measures are often needed on sloping fields and where wind erosion is a problem.

Grass waterways rank first in prevention of erosion and the control of runoff water from cultivated land. They are usually located in the natural drainage ways, but they may be constructed along field boundaries in some cases. Waterways are best made dished or saucer-shaped and rather shallow to keep water from concentrating to any great depth. Width should be sufficient to carry heavy rains without overflowing. A dense vegetative cover is required to keep the water from cutting a gully through the centre. Grasses that make a dense sod are preferred for this purpose.

Where a waterway discharges into an open ditch or stream at a lower level, some sort of structure is needed to keep the overfall from cutting a gully back into the waterway. These structures usually are constructed of concrete or masonry. Earth dams often are built across a large drainage way to prevent gullying and to form a pond for water supply, wildlife and recreation.

Contour tillage is one of the simpler practices that reduce soil losses about 50% from those occurring with up-and-down hill cultivation. In contouring, all furrows and rows follow around the slope and are level from end to end. The ridges left by farm machinery in preparing the soil and cultivating the crop act as small dams, holding back the water and giving it time to soak into the ground. Contour guide lines may easily be laid out by the use of a simple level fitted with sights. (*See* also CONTOUR FARMING.)

On longer slopes, contour strip-cropping has proved very effective. Instead of the entire slopes being planted in one crop, as in simple contouring, strips of row crops are planted between strips of close-growing crops such as small grains or meadow. If the contour ridges in the cultivated crop are overtopped in a hard storm, the close-growing strip below will slow down the water and catch much of the soil it carries. Strip-cropping has been found to reduce soil losses about 75%.

Terraces are widely used, especially on long slopes, and give the most effective control if they are properly laid out and constructed and are given good care. A terrace is a low, flat ridge of earth built across the slope, with a channel for runoff water just above the ridge. Usually terraces are built on a slight grade so that the water caught in the channel moves slowly toward the terrace outlet. Where several terraces are used on a long slope they have the effect of breaking it up into a series of short slopes that lose less soil than one long one. Terrace cultivation, of course, has long been practiced, for example in China, Japan, the Philippines, and other areas of Oceania and Southeast Asia; around the Mediterranean; and in the Andes of South America. In areas where soils are able to take in water readily and rainfall is relatively low, level terraces may be used. These terraces merely impound the excess water until it can have time to soak into the soil.

Diversion terraces, or diversions, are built in the same way as field terraces, but they are somewhat larger. They are often used to protect hillside fields from water falling on land above them, or to take water away from a gully and thus assist in controlling it. The practices already discussed are the major ones used in the control of erosion by water. Additional practices in use on farms and ranches include land contouring or leveling for irrigation, irrigation water management, diversion construction, and pond construction. Watershed projects include floodwater retarding and diversion structures, grade stabilization structures, silt and debris basins, and stream channel improvement.

Wind erosion control requires a somewhat different technique, which involves the following practices:

FIG. 7.—EROSION CONTROL PRACTICES

(Left) Contour strip-cropping with alternate strips of close-growing grass-legume and corn, the row crop; (above) narrow base terraces, each occupying as much space as three rows of corn; (below) grass waterway planted with thick grass

1. Protecting the soil surface with cover, usually vegetation. Tillage methods, called mulch tillage or stubble mulching, in which crop residues are kept on or in the surface of the soil, have proved effective.

2. Keeping the surface of the soil rough to slow down the wind and trap drifting soil.

3. Managing the soil so as to produce soil aggregates large enough to resist wind action.

4. Using barriers, such as crop strips, ridges, or field windbreaks to trap the drifting soil and keep it from spreading.

See also DRY FARMING.

9. Worldwide Conservation.—By the middle of the 20th century, conservation had gained support throughout the world. The conservation movement in the United States has been widely studied and the programs of many nations have been patterned after it. The United States has sent many technicians abroad to study erosion problems and suggest courses of action. This work is carried forward through programs of international cooperation and assistance. An extensive training program for technicians from various lands was established through the U.S. Soil Conservation Service. Several hundred specialists from most of the countries of the world have been trained in this manner.

A publication of the Soil Conservation Service (*Misc. Pub. 908*, 1962) contains a world map indicating the countries carrying on soil and water conservation works and programs. Fifteen countries shown as conducting special programs, nationwide in scope, are: United States, Mexico, Colombia, Venezuela, Spain, Crete, Kenya, Northern Rhodesia (now Zambia), Tunisia, South Africa, Jordan, India, Pakistan, Australia, and Philippines. Twenty-nine other countries have soil and water conservation incorporated in agriculture, public works, or other national programs. Nine additional countries have local soil and water conservation programs or projects, provincial or state, or subsidiary to research or educational programs.

SOIL ANALYSIS: *see* SOIL: *Soil Testing and Analysis.*

SOIL MECHANICS is the branch of engineering science dealing with the behaviour of soil when subjected to stresses or to the action of percolating water. The subject furnishes a rational basis for foundation engineering and earth-dam design and provides new tools for geological investigation.

Soil is a natural aggregate of mineral grains, with or without organic constituents, that can be separated by gentle mechanical means such as agitation in water. It may consist of the products of rock decomposition found essentially in their original position after weathering, or of materials transported and deposited by glaciers, streams or wind. Soil differs from most structural materials in that it consists of three phases: solid mineral matter, water, and air or other gas. Many soils comprise two-phase systems, of mineral matter and water, and are then said to be saturated.

Principle of Effective Stress.—Although soils constitute possibly the oldest construction materials known to man, the arts of foundation and earth-dam engineering remained essentially empirical until about the third decade of the 20th century, largely because the implications of the interaction between the soil grains and water had not been correctly evaluated. In 1923 Karl Terzaghi published the first clear statement of the principle of effective stress, a concept that proved to be the key to an understanding of the engineering behaviour of soils. According to this principle, the intensity of stress p acting normal to any section through a mass of soil is equal to the sum of two parts, the intergranular or effective stress p' which is transmitted from grain to grain at points of contact, and the neutral or pore stress u which is transmitted through the water in the pore space; that is,

$$p = p' + u \tag{1}$$

Moreover, the engineering behaviour of the mass of soil is exclusively a function of the intergranular stress and is unaffected by the neutral stress.

The significance of the principle of effective stress is illustrated in connection with the strength of saturated cohesionless granular materials such as sand or gravel. As early as 1773, C. A. Coulomb expressed the resistance s possessed by such a material against failure by sliding as

$$s = p \tan \phi \tag{2}$$

where p was the pressure per unit area normal to the section along which sliding took place and ϕ the angle of repose of the material. The quantity ϕ, now more precisely designated as the angle of internal friction, is a soil property depending somewhat on the kind and shape of the mineral grains and primarily on the looseness or denseness of the arrangement of the grains. It may range between about 30° and 44°. Since slopes subjected to percolating water often proved less stable than those on dry sand, it was commonly assumed that the values of ϕ for wet sand were at least 6° smaller than those for dry sand. Yet, direct shear tests by Terzaghi indicated essentially identical values in either state. The discrepancy was resolved by replacing p by p' in equation (2), whence

$$s = p' \tan \phi = (p - u) \tan \phi \tag{3}$$

In this form, Coulomb's equation is valid.

Curiously enough, Coulomb himself made no measurements to determine ϕ and assumed a value of 45° in his application of equation (2). Indeed, until the principle of effective stress was understood, meaningful tests of the physical properties of soils could not be performed.

Seepage Pressure.—If water flows through a deposit of sand, the viscous drag tends to move the grains in the direction of the flow and produces a force, known as a seepage pressure, between the grains. The seepage pressure is an intergranular stress. If upward flowing water produces a seepage pressure just equal and opposite to the submerged weight of the sand above a given horizontal section, the intergranular pressure becomes zero and, according to equation (3), the strength of the sand becomes zero. The sand is said to be in a "quick" condition and is incapable of supporting a load on its surface.

Where flowing water emerges from a cohesionless deposit the seepage pressure has a component directed outward and away from the surface and tends to dislodge and remove some of the smaller particles. If the process continues, a tunnel-shaped cavity

or "pipe" may develop. The formation of such pipes beneath or within dams has led to several catastrophic failures. It may be prevented by blanketing the surface where the seepage emerges with coarser materials that permit escape of the water but prevent erosion of the fines. If the seepage pressure has a great enough upward component, it may be necessary to add weight to the top of the filter to counterbalance the upward forces.

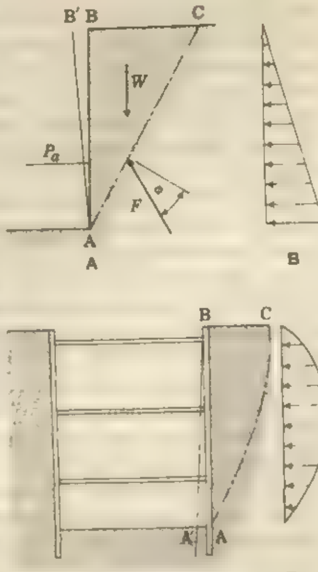

FIG. 1.—SHEARING RESISTANCE
(A) Forces assumed by Coulomb in calculating earth pressure against retaining wall; (B) distribution of pressure against wall; (C) braced cut; (D) distribution of earth pressure against sheeting

Shearing Resistance.—The shearing resistance of soil is a primary factor in several problems of engineering importance. It governs the pressure against retaining walls, bulkheads and the timbering of braced cuts. It also determines the bearing capacity of footings and piles and the stability of slopes, embankments and dams.

One of the first problems to receive attention in soil mechanics was the calculation of the pressure of earth against retaining walls. Coulomb solved the problem by considering the equilibrium of a triangular wedge of earth behind the wall (fig. 1[A]). He assumed the surface of sliding AC to be plane. The resultant force F on the surface of sliding was assigned the inclination ϕ to the normal to the surface, implying fully developed shearing resistance along AC. By allowing the inclination of AC to vary, Coulomb found the plane on which slip was most likely to occur, and the corresponding value of earth pressure P_a, designated as the active earth pressure. He assumed this pressure to act horizontally at the lower third point of the wall.

Coulomb's theory proved, with slight modifications, to be satisfactory for ordinary retaining walls and is widely used today. However, it failed to account for the pressures that practical men observed against the bracing of open cuts. Experience indicated that the load in the upper braces was substantially greater than that given by the theory, whereas the bracing at the bottom was very lightly loaded.

Theorists generally ignored these observations, and practical men generally discounted the theories. The state of contradiction was not clarified until in 1920 Terzaghi recognized the great importance of the manner in which the support may yield. In connection with a retaining wall, the supporting surface AB yields into the position AB′ and permits a uniform degree of lateral expansion in the entire sliding wedge ABC; the resulting lateral pressure increases linearly with depth (fig. 1[B]). On the other hand, in a braced cut, lateral expansion of the upper part of the wedge is restricted as soon as the uppermost brace is set; the deformation of the sheeting is likely to resemble BA′ in fig. 1(C). The large expansion at the bottom of the wedge is associated with a reduction of pressure at the bottom of the cut and an increase at higher levels. The corresponding pressure distribution is roughly parabolic (fig. 1[D]). Moreover, the surface of sliding is no longer plane but is curved. The general wedge theory of earth pressure (Terzaghi, 1939) took account of these factors and provided the means for calculating the loads in temporary bracing systems. The theory was confirmed by full-scale measurements on the bracing of the Berlin subway. Subsequently, it was found applicable to clay soils and confirmed by numerous full-scale field measurements, including a series on the Chicago subway.

Slope Stability.—Closely related to problems in earth pressure are those dealing with the stability of slopes. Before about 1920 it was assumed that every soil possessed an angle of repose and that slopes would be stable if established at angles slightly smaller than the appropriate angles of repose tabulated in various handbooks. Occasional catastrophic slides, particularly in clay soils, indicated from time to time the inadequacy of the procedure. In particular, a series of slides on the Swedish state railways near the beginning of the 20th century, culminating in one with a loss of 41 lives, led to the appointment of a Royal Swedish Geotechnical commission to study the degree of safety of existing slopes and to suggest remedial and precautionary measures. The report of the commission, published in 1922, contained the most complete analysis of landslides up to that time. It made the first extensive use of what is now called the Swedish method of stability analysis. The method is based on the empirical observation that the surface on which a slide occurs is almost always an approximately circular arc. The principle of the method is shown in fig. 2. The mass ABC tends to rotate about O under the influence of the weight W_1. The rotation is resisted by the moment of W_2 and by the moment of the shearing resistances s acting along the circular arc AC. The value of s required to prevent a failure (factor of safety = 1) is

$$s = \frac{W_1 l_1 - W_2 l_2}{R\widehat{AC}} \tag{4}$$

The factor of safety of the slope may be determined by comparing s from equation (4) with the value of shearing strength determined by laboratory or field tests. The position of the surface of sliding for which the factor of safety is a minimum is found by successive trials.

Most currently used procedures for stability analysis are derived from the Swedish method. Since slides frequently occur in clayey soils, information is needed regarding the shearing strength of clays. Coulomb expressed the relation between shearing strength s and normal pressure on surface of sliding as

$$s = c + p \tan \phi \tag{5}$$

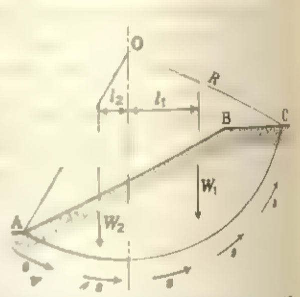

FIG. 2.—FORCES TENDING TO CAUSE AND PREVENT FAILURE OF A SLOPE ALONG A CYLINDRICAL SURFACE

where c was called the cohesion, or the shearing strength at zero normal pressure, and the other symbols have the same meaning as in equation (2). However, even with the replacement of p by p', equation (1), Coulomb's equation was found to be inadequate because the value of s was found to be a function of the loading history of the clay. Research has not yet fully clarified this aspect of the subject. For saturated clays that do not experience change in water content under stress, however, the shearing strength with respect to total stresses is independent of the pressure. That is, such clays behave as frictionless materials and their strength is

$$s = c = q_u/2 \tag{6}$$

where q_u is the ultimate strength of a cylindrical or prismatic specimen tested axially in a simple compression test. Many problems of practical importance can be treated in this manner.

Settling of Structures.—The settling of structures located above deep beds of soft clay long proved baffling to foundation engineers, particularly since such settlings often continued to increase many years after completion of the structures. Inasmuch as the damaging effects of the settling often did not develop until the settling had reached an advanced state, buildings frequently appeared to crack and deteriorate spontaneously. Several engineers had suspected that the settling was the result of slow squeezing of the water from the pores of the clay, but no satisfactory quantitative explanation was available until Terzaghi proposed the theory of consolidation in 1923. According to this theory, clay consists of mineral particles arranged in a structure that is at once relatively compressible and fairly impermeable. The voids between the mineral particles may constitute an appreciable fraction of the total volume, but the openings between

the voids are very small and restrict the flow of water. The voids are considered to be filled with water, which is inherently less compressible than the mineral skeleton. Hence, a load when first applied to the clay soil is carried almost exclusively by the water. The compression of the clay structure, and hence the settling of the ground surface, take place, in accordance with the principle of effective stress, only as the stress is transferred from the water to the clay structure.

Terzaghi proposed an instructive analogue to the process of consolidation of clay. In its simplest form, it consists of a water-filled cylindrical container closed by a piston supported by a spring. The spring represents the clay skeleton. The piston represents the boundary between two void spaces in the clay. It is pierced by a hole AB which permits escape of water at a slow rate corresponding to the low permeability of clay. If a load P is suddenly placed on the piston, no shortening of the spring can occur at the first instant because no water has yet escaped from the cylinder. Since the spring must shorten to carry additional load, the load P must produce an additional pressure P/A in the water, and the pressure gauge will indicate this value. There is now set up across the opening AB a pressure differential equal to P/A, which produces a flow of water from the chamber. As the water flows out the spring correspondingly shortens and carries load in proportion to its shortening. With the spring carrying part of the load, the pressure in the water is less than P/A. The pressure differential across AB is reduced, the rate of flow decreases and the rate of settling decreases. The process continues at a decreasing rate until, after a very great time, the excess pressure in the water approaches zero. The rate of settling of the piston corresponds to the rate of transfer of the total stress P/A from the water to the spring. By analogy, the rate of settling of a clay stratum is governed by the rate of transfer of the total pressure caused by the construction from porewater pressure to intergranular or effective pressure. The rate of transfer, in turn, is a function of the compressibility of the soil structure, the permeability of the clay and the viscosity of the water.

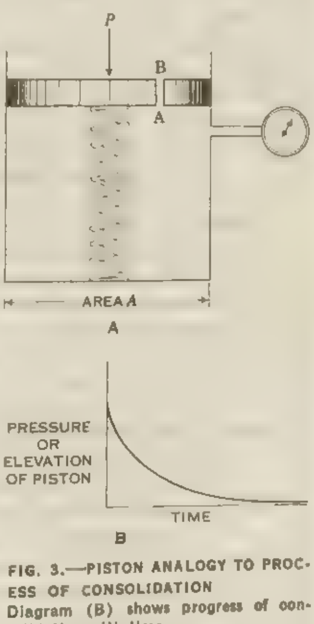

FIG. 3.—PISTON ANALOGY TO PROCESS OF CONSOLIDATION
Diagram (B) shows progress of consolidation with time

The mechanism of consolidation provides an explanation for several hitherto unexplained phenomena, including the settling of the ground surface associated with pumping from underlying aquifers. The reduction in pore pressure associated with pumping induces consolidation of any clay layers above or below the aquifer. Large settlings due to this phenomenon have occurred at many places, including Mexico City and the Santa Clara valley in California.

The accuracy with which settlings can be predicted on the basis of soil mechanics varies to a considerable extent with the geology and character of the deposits involved. Under the most favourable circumstances, computed and observed settlings agree satisfactorily until the settling reaches about 60% of the computed final value. Thereafter the real settlings are likely to exceed the computed ones by an amount that is usually, but not always, a small fraction of the total settling. The additional settling partakes of the character of a slow creep; the discrepancy is greatest for highly organic soils.

Sampling and Testing.—The structure of most compressible soils is sensitive to disturbance. If the samples from which values of compressibility and other physical properties are determined have experienced disturbance, the predictions based on the test values may be seriously in error. To avoid this difficulty, drilling and sampling techniques have been devised to permit procurement of specimens as undisturbed as possible. The most refined samplers consist of thin-walled tubes that are pushed steadily, without driving, into the ground, with an internal piston that remains at a fixed elevation such that the length of sample recovered is equal to the distance of penetration. Techniques have been developed for investigating the properties of the soils *in situ;* research is actively being conducted in this field. Nevertheless, errors due to disturbance remain significant; their evaluation requires full-scale field observations.

The greatest source of error in the application of soil mechanics lies in the heterogeneous character of most natural soil deposits. The products of natural processes are almost always complex and cannot economically be investigated in sufficient detail to determine soil properties completely. In some instances, only average values can be estimated, together with probable variations from the average. Nevertheless, useful predictions of settlement and other aspects of engineering behaviour can be derived from such estimates and the principles of soil mechanics.

See Karl Terzaghi, "Origin and Functions of Soil Mechanics," *Trans. Amer. Soc. Civ. Engrs.*, vol. CT, pp. 666–696, which contains extensive bibliography (1953); Karl Terzaghi and Ralph B. Peck, *Soil Mechanics in Engineering Practice* (1948). (R. B. P.)

SOISSONS, COMTES DE, nobles and princes important in French history. The Soissonnais, or country round Soissons, became an hereditary countship in the early period of feudalism. Having been held successively by the Houses of Vermandois, Eu, Nesle, Hainaut, Châtillon, and Coucy, it was shared, early in the 15th century, by those of Bar and Orléans. The Orléans rights to it were granted by King Louis XII to his daughter Claude, whose son, King Henry II, finally reunited them with the French crown, but the Bar rights passed by marriage (1435) to the House of Luxembourg. Marie de Luxembourg, comtesse de Soissons, who died in 1547 as the widow of François de Bourbon, comte de Vendôme (1470–95; *see* BOURBON: Table III), left the title to her grandson Jean. When he was killed in the Battle of Saint-Quentin (1557), his rights passed to his brother Louis I, prince de Condé (d. 1569).

Louis de Condé left the title of comte de Soissons to his youngest son, Charles (1566–1612). This comte fought for Henry of Navarre (later Henry IV of France) against Henry III of France at Coutras (1587), for Henry III against the Holy League in Brittany (1589), and finally for Henry IV against the League in Normandy (1590–92) and against Savoy (1600). His desire to marry Henry IV's sister Catherine was frustrated. Governor of Dauphiné from 1601, he protested when Marie (*q.v.*) de Médicis was named regent in 1610; but he was appeased with the governorship of Normandy. He died at Blandy-en-Brie on Nov. 1, 1612, leaving a son and three daughters by his marriage (1601) to Anne de Montafié.

As the princes de Condé (*q.v.*) came to be called simply Monsieur le Prince, so Charles was called simply Monsieur le Comte. His son Louis (1604–41) inherited this designation with the title comte de Soissons. After taking the side of Marie de Médicis in 1620, he served Louis XIII against the Huguenots in 1622. Involved in intrigues against the cardinal de Richelieu (*q.v.*), he is alleged to have plotted to assassinate him at Amiens in 1636, after a campaign against the Spaniards in Picardy (*see* THIRTY YEARS' WAR). In 1637 he fled to Sedan, just across France's eastern frontier; other malcontents joined him; and in 1641 he published a manifesto against Richelieu and invaded France with a Habsburg army. He defeated the marshal de Châtillon (Gaspard III de Coligny) at La Marfée on July 6, 1641, but was killed by a mysterious shot at the moment of his victory.

The rebel's surviving sister, Marie, had married Thomas of Savoy, prince of Carignano (*see* SAVOY, HOUSE OF) in 1625. Their youngest son, Eugène Maurice de Savoie-Carignan (1633–73), who married Cardinal Mazarin's niece Olimpia (Olympe) Mancini in 1657, assumed the title comte de Soissons and served in Louis XIV's armies. The comtesse, after a brief liaison with Louis XIV, had to leave France suddenly in 1680 to avoid interrogation over the Affair of the Poisons (*q.v.*); the allegation that

she poisoned the queen of Spain, Maria Luisa of Orléans, in 1689, is discredited. Her eldest son Louis Thomas (1658–1702), comte de Soissons from 1673, followed his brother, the famous Prince Eugene (*q.v.*) of Savoy, into the Austrian service in 1695. His grandson Eugène Jean François (1714–34), duke of Troppau and, from 1729, titular comte de Soissons, died childless.

In 1888 King Humbert I of Italy granted the title of conti di Villafranca-Soissons to the issue of Prince Eugenio Emanuele of Savoy-Carignano (1816–88; a member of a junior branch of the senior line of Thomas of Carignano's descendants) by his morganatic marriage (1863) to Felicita Crosio.

SOISSONS, a city of France, capital of an *arrondissement* in the *département* of Aisne, Picardy region, 60 mi. (97 km.) NE of Paris by road. Pop. (1962) 22,890. The city, surrounded by wooded hills, stands on the left bank of the Aisne, the suburb of Saint-Vaast lying on the right bank. The Cathedral of Saint-Gervais and Saint-Protais, partly ruined in World War I, was begun in the second half of the 12th century and finished toward the end of the 13th. It is 328 ft. (100 m.) long and 87 ft. (26.5 m.) wide, and the vaulting of the triple nave is 100 ft. (30.5 m.) above the pavement. The single tower dates from the middle of the 13th century and is an imitation of those of Notre Dame of Paris at a height of 216.5 ft. (66 m.). The south transept, the oldest and most graceful portion of the building, terminates in an apse. The facade of the north transept dates from the end of the 13th century. The apse and choir retain some fine 13th-century glass.

Considerable remains exist of the magnificent Abbey of Saint-Jean-des-Vignes, where Thomas Becket resided for a time. These include the ruins of two cloisters (the larger dating from the 13th century), the refectory, and above all the imposing facade of the church (restored). Above the three portals (13th century) runs a gallery, over which is a large window; the two unequal towers (the higher being 256 ft. [78 m.]) of the 15th and early 16th centuries are surmounted by beautiful stone spires, which command the town. The former abbey church of Saint-Léger, which belongs to the 13th century, now houses a museum.

The wealthiest of all the abbeys in Soissons, and one of the most important of all France during the first two dynasties, was that of Saint-Médard, in the Saint-Vaast district, founded about 560 by Clotaire I, beside the villa of Syagrius, which had become the palace of the Frankish kings. St. Médard, apostle of Vermandois, and kings Clotaire and Sigebert were buried in the monastery. It was there that Childeric III, the last Merovingian, was deposed, Pepin (Pippin) III the Short was crowned by the papal legate, and Louis the Pious was kept in captivity in 833. In 1530 Saint-Médard was visited by a procession of 300,000 pilgrims. But the religious wars ruined the abbey and, although it was restored by the Benedictines in 1637, it never recovered its former splendour. Now only the crypt, dating from around 840, remains.

Soissons is an important road junction and on the Paris-Laon railway. Among the industrial establishments are iron and copper foundries and factories, producing boilers, agricultural implements and other iron goods, rubber goods, cardboard and packaging materials, glass, enamel, and sugar. There is a large trade in grain for the provisioning of Paris.

History.—Soissons is generally identified with the oppidum of Gallia Belgica, called Noviodunum by Caesar. Noviodunum was the capital of the Suessiones, who occupied 12 towns, and whose king, Divitiacus, one of the most powerful in Gaul, had extended his authority even beyond the sea among the Britons. In 58 B.C. Galba, king of the Suessiones, separated from the confederation of the Belgians and submitted to the Romans. At the beginning of the empire Noviodunum took the name of Augusta Suessionum, and afterward that of Suessiona, and became the second capital of Gallia Belgica, of which Reims was the metropolis. The town was before long surrounded with a wall and defended by a citadel, and it became the starting point of several military roads.

Christianity was introduced by St. Crispin and St. Crispinian, who were martyred in *c.* 286 but whose work was continued by St. Sinitius, the first bishop of Soissons. After the barbarians had crossed the Rhine and the Meuse Soissons became the metropolis of the Roman possessions in northern Gaul, and on the defeat of Syagrius by Clovis in 486, the Franks seized the town. It was at Soissons that Clovis married Clotilde, and, though he later settled in Paris, Soissons was the capital of his son Clotaire I, and afterward of Chilperic I, king of Neustria. In the time of Chilperic's son, Clotaire II, the kingdom of Soissons was incorporated with that of Paris. Louis the Pious did penance there after being deposed by the assembly at Compiègne.

Under Charles the Fat (886) the Normans failed to win the town, but laid waste Saint-Médard and the neighbourhood. In 923 Charles the Simple was defeated outside the walls by the supporters of Rudolph of Burgundy, and Hugh the Great besieged and partly burned the town in 948. Under the first Capets Soissons was held by hereditary counts. (*See* SOISSONS, COMTES DE.)

The communal charter of the town dates from 1131. At a synod held at Soissons in 1121 the teachings of Abelard were condemned and he was forced to retract them. In 1155, at an assembly of prelates and barons held at Soissons, Louis VII issued a famous decree forbidding all private wars for a space of ten years; and in 1325 Charles the Fair replaced the mayor of Soissons by a royal provost dependent on the bailiwick of Vermandois.

The town suffered severely during the Hundred Years' War, in 1414, when it was held by the Burgundians, it was captured and sacked by the Armagnacs under the dauphin. The Treaty of Arras (1435) brought it again under the royal authority. It was sacked by Charles V in 1544 and in 1565 by the Huguenots.

In 1814 Soissons was captured and recaptured by the Allies and the French. In 1815, after Waterloo, it was a temporary rallying point for the vanquished. In 1870 it capitulated to the Germans after a bombardment of three days.

During World War I Soissons was for most of the time just behind the Franco-British lines, but the Germans overran it in 1918 in their thrust for Paris (May 27); it was retaken in the Franco-British offensive of July 18, 1918. In World War II the town sustained some damage, and the bridges were blown up and the railway station completely destroyed by the explosion of a U.S. munitions train.

SOKOLLU (SOKOLLI) **MOHAMMED PASHA** (1505–1579), one of the most celebrated of the Ottoman grand viziers, was born at the village of Sokol in Bosnia. Recruited into the Ottoman service through the *devshirme* (child-tribute) levied in the Balkan lands, he was educated at the Porte during the earlier years of the reign of Sultan Suleiman the Magnificent (1520–66). He became *kapudan pasha* (high admiral of the Ottoman fleet) in 1546 and then *beylerbeyi* (governor-general) of Rumeli. During his tenure of this latter office he conquered Temesvár in Hungary (1552). He also took part in the third campaign of Sultan Suleiman against Persia in 1554–55, being raised thereafter to the rank of vizier. Mohammed Pasha commanded the forces of Selim during the conflict (1559–61) between Selim and Bayazid, the sons of Sultan Suleiman, over the succession to the throne and in 1562 received in marriage the hand of Esmi-Khan, a daughter of Selim. He was made grand vizier in June 1565 and retained this office until his death in October 1579. During the 14 years and more of his grand vizierate he became in effect the real ruler of the empire, although he had to face powerful influences which opposed his personal domination and the policies that he advocated. The main event during his tenure of the grand vizierate was the war against Venice (1570–73) which led to the Ottoman conquest of Cyprus. Mohammed Pasha was in general inclined to maintain peaceful relations with foreign powers. Reluctant to enter into the war with Venice, he also opposed the decision to begin a new conflict (1578–90) against Persia. After the death of Sultan Selim II in 1574, however, his influence at the Porte became much diminished. Mohammed Pasha was assassinated in Istanbul on Oct. 11, 1579. (V. J. P.)

SOKOLOW, NAHUM (1861–1936), Jewish writer and Zionist leader, was president of the World Zionist Organization and of the Jewish Agency (1931–35) and chairman of the World Zionist Executive (1922–31). Descendant of an ancient rabbinical family in Poland, he was born at Wyszogrod on Feb. 3, 1861. He displayed remarkable gifts as a writer and scholar at an early age and was well-known by his contributions to the Jewish

press in Hebrew and other languages. At 24 he became assistant editor of the Hebrew scientific weekly *Ha-Zefirah* in Warsaw and later its editor, transforming it into a modern daily newspaper with wide circulation. He also edited in Warsaw the literary and historical periodicals *Ha-Asif* and *Sefer Ha-Shanah* (1885–1902).

In 1897 Sokolow joined the Zionist Organization. In 1906 he became its secretary general and editor of its official organs *Die Welt* and the Hebrew weekly *Ha-Olam.* He traveled all over the world propagating Zionist ideas. After the outbreak of World War I he went to England, becoming later a naturalized British subject. He took a prominent part in Anglo-French negotiations leading to the Balfour declaration of Nov. 2, 1917 (*see* ZIONISM). Sokolow secured similar declarations in favour of a Jewish National Home from France, Italy, Poland, South Africa, and other countries. In May 1917 Sokolow was received in the Vatican by Pope Benedict XV, who expressed his sympathy for the Zionist cause.

At the Paris Peace Conference of 1919 Sokolow led the Zionist delegation and later was instrumental in obtaining minority rights for the Jews in some East European countries. He died in London on May 17, 1936. In 1960 his remains were transferred to Israel.

His numerous writings include *The History of Zionism, 1600–1918,* 2 vol. (1919); *Hibbath Zion* ("Love of Zion," 1934); *Baruch Spinoza u-Zemano* ("Spinoza and his Time," 1928–29); *Yischim* (biographical essays), 3 vol. (1911–35).

See *Sefer Sokolow,* in Hebrew (1960); S. Kling, *Nachum Sokolow* (1960). (C. So.)

SOKOTO, a town and provincial capital of Northern Nigeria, Africa, lies on the south bank of the Sokoto River, about 621 mi. (1,000 km.) NNE of Lagos by road, at approximately 500 ft. (152 m.) above sea level. Situated in a well-populated area, Sokoto is the most northerly of the larger towns of Nigeria. Pop. (1963) 89,817. To the north of the river the land develops into rolling sand dunes that merge into the desert across the border in the Republic of Niger. West of Sokoto the Rima River joins the Sokoto and creates a fertile area around the town.

In the 1820s Sokoto was adopted as his capital by Sultan Bello, one of the sons of Shehu Usman Dan Fodio, after the successful *jihad* (holy war) which had placed the Fulani dynasties in control of Northern Nigeria. Sokoto was recognized by the Fulani amirs as the capital of the empire and the sultans of Sokoto have since continued to be regarded as the *sarkin mussulmi* or leaders of all Muslims in the western Sudan. The tomb of Dan Fodio and other holy shrines have made the town a place of pilgrimage.

Sokoto is a typical Hausa-Fulani town of mud dwellings, though the more prosperous merchants build houses faced with concrete. The sultan's palace is in the centre of the town, close by the mosque of the Shehu. Houses are generally grouped in compounds with a retaining wall within the main wall of the town. The Sokoto River is subject to periodic flooding which made it necessary to construct an approach road to the town over a raised causeway. Sokoto lies virtually at the northwestern end of Nigeria's internal system of communications. There is an airstrip which has connections with Kaduna to the east and a tarmac road links Sokoto with Kano, via Gusau, where a branch of the Nigerian Railway passes en route to Kaura Namoda, the railhead. There are road links southward to Argungu and Birnin Kebbi and thence to Yelwa on the Niger. There is also a road to the north into the desert where it joins up with the ancient caravan routes.

Sokoto is an important centre of commerce for an area extending far into the western Sudan. The famous red goats of Sokoto supply the leather of the incomparable moroccan leather work while Sokoto itself has a flourishing tanning and dyeing leather industry. There is also hand weaving and pottery, and large numbers of people are engaged in fishing on the Sokoto River and in agricultural pursuits. Caravans from the north bring in salt and potash from the desert, the potash being required for the tanning of leather. To the west of Sokoto successful experiments are being carried out for the cultivation of rice. Sokoto provides a meeting place and commercial exchange centre for the desert tribes and for pilgrims, who come from as far away as Ilorin and Katagum, and in exchange for the salt and potash take away the palm oil, kola nuts, soap, and cloth produced further south.

(W. H. I.)

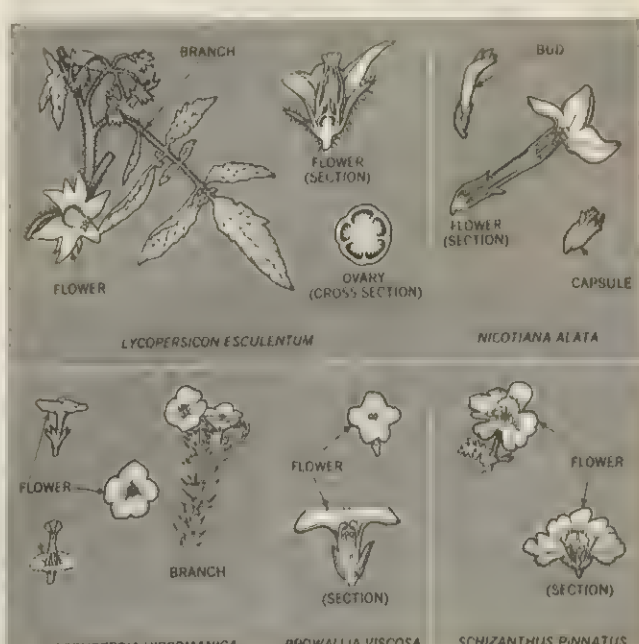
SOL, the sun, a name given to two distinct deities at Rome. The original Sol, or Sol Indiges, had a shrine on the Quirinal and an annual sacrifice on Aug. 9. The worship appears to be native. The Roman poets, however, equate him with the Greek Helios.

The worship of Sol assumes an entirely different character with the later importation of various sun cults (*e.g.,* Mithraism; *q.v.*) from the east (Syria). Elagabalus (*q.v.*) built a temple to him as Sol Invictus on the Palatine and attempted to make his worship the principal religion at Rome. Aurelian reestablished the worship and erected a magnificent temple to Sol in the Campus Agrippae. The worship of Sol as special protector of the emperors and the empire remained the chief imperial cult until Christianity replaced it. (R. B. LD.)

SOLANACEAE, the nightshade family of plants, of considerable economic importance, includes a number of species that produce food and drug narcotics or are used as fumitories or ornamentals. Prominent among these are the potato and eggplant (*Solanum*), tomato (*Lycopersicon*), garden pepper (*Capsicum*), tobacco (*Nicotiana*), belladonna (*Atropa*), thorn apple (*Datura*), and henbane (*Hyoscyamus*). Some of the genera that contain ornamental species are *Petunia, Lycium, Solanum, Nicotiana, Datura, Salpiglossis, Browallia, Brunfelsia, Cestrum, Schizanthus, Solandra, Streptosolen,* and *Nierembergia.*

This family of dicotyledons belongs to the order Tubiflorae. It includes about 90 genera with approximately 2,800 species, which, though found throughout the world except in polar regions, are most abundant and widely distributed in the tropical regions of Latin America, where about 40 genera are endemic. Very few are to be found in temperate regions, and about 50 species are found in North America, north of Mexico. Only four species in three genera are known from Britain. The genus *Solanum,* which embraces more than two-thirds of all the species in the family, includes all the wild potatoes, which are distributed primarily at high elevations in the mountains from Utah and Colorado southward through Mexico and Central and South America. Some of these wild potatoes, especially *Solanum demissum* of Mexico, have been widely used in the improvement of the domesticated potato.

Alkaloids, especially the glucosidal alkaloid solanine, are the narcotic-poisonous principles prevalent in many of the species. These have given the family its sombre vernacular name "nightshade." The alkaloids are of increasing interest and importance to the



FROM L. BAILEY, "MANUAL OF CULTIVATED PLANTS," 1949; THE MACMILLAN CO.

REPRESENTATIVES OF THE FAMILY SOLANACEAE

chemical and pharmaceutical industries. Many species in the Solanaceae have been used by primitive people in various parts of the world in their folklore and therapeutic practices.

Included in the family are annual herbs, as *Solanum nigrum*, a common weed in waste places, and perennial herbs, as *Atropa belladonna*, the deadly nightshade; shrubs, as *Lycium halimifolium*, an old-fashioned garden plant; small trees, as *Datura sanguinea*, a South American ornamental with large reddish flowers; lianas, as *Solanum juglandifolium*, a showy rampant vine of South America; and prostrate creepers, as some Latin-American species of *Solanum*. The alternate leaves (or sometimes opposite near the inflorescence) are simple and entire, as in most species of *Lycium*, or are variously dissected, as represented by the extreme condition found in various species of *Lycopersicon* (tomato). The flowers are usually borne in extra-axillary cymes.

The hermaphroditic, generally regular, flowers have their parts in fives—five sepals, five petals, five stamens, all in alternating whorls. There are two carpels, which are generally placed obliquely. The corolla is regular and rotate, as in *Solanum tuberosum*, or bell shaped, as in *Datura* and *Atropa*, or somewhat irregular as in *Hyoscyamus;* in the tribe Salpiglossideae, which forms a link with the closely allied family Scrophulariaceae (*q.v.*), it is zygomorphic, forming, as in *Schizanthus*, a two-lipped flower. The stamens are inserted on the corolla tube and alternate with its lobes; in zygomorphic flowers only two or four fertile stamens are present. The flowers are generally conspicuous, and honey is secreted on the disk at the base of the ovary or at the bottom of the corolla tube between the stamens. The ovary is usually bilocular but in *Capsicum* becomes unilocular above, while in some cases an ingrowth of a secondary septum makes it four celled, as in *Datura*, or irregularly three to five celled, as in *Nicandra*. The anatropous ovules are generally numerous on swollen axile placentae. The style is simple and bears a bilobed or capitate stigma. The fruit is a many-seeded berry, as in *Solanum*, or capsule, as in *Datura*, where it splits lengthwise, and *Hyoscyamus*, where it opens by a transverse lid forming a pyxidium. The embryo is bent or straight and embedded in endosperm. The persistent calyx may serve to protect the fruit or aid in its distribution, as in the bladdery structure enveloping the fruit of *Physalis*.

Some additional species of less importance than those already considered are *Physalis alkekengi* (winter cherry) and *P. peruviana* (cape gooseberry); *Lycopersicon pimpinellifolium* (currant tomato) and *Cyphomandra betacea* (tree tomato), both of South America; *Datura metel* of India and *D. meteloides* of southwestern United States, large-flowered annuals that are grown in gardens in warm-temperate countries, as are the treelike shrubs *D. suaveolens* of Brazil and *D. arborea* of the central Andes; *Solanum muricatum* (pepino), *S. pseudocapsicum* (Jerusalem cherry), and *S. integrifolium* (scarlet eggplant), also cultivated for their fruits and aesthetic appearance. (D. S. Cl.)

SOLAR ENERGY, UTILIZATION OF. Energy is radiated from the sun at the rate of about 43,000 kw. per square metre of solar surface. Solar radiation occupies only the small portion of the electromagnetic spectrum between 0.22 and 3.3 microns (μ). The invisibly short but potent ultraviolet waves below 0.4μ carry 9% of the incoming solar energy, while the invisible infrared heat waves beyond 0.7μ are responsible for 50% of the total. The "light" waves between these limits convey the remaining 41%, including the maximum intensity radiation at 0.48μ in the green portion of the visible spectrum. Both the amount and the spectral distribution of the energy radiated from the sun indicate that the effective temperature of its surface is close to 6,000° C (10,800° F).

Solar radiation falling on a surface normal to the sun's rays at the outer limit of the earth's atmosphere has an average intensity of 2 (±2%) cal. per minute per square centimetre (1.41 kw. per square metre; 445 BTU per hour per square foot). This quantity, known as the solar constant, has apparently remained virtually unchanged, except for periodic minor variations, for several billion years. Only about 46% of the incoming solar energy actually reaches the earth's surface, since, on the average, 35% is reflected back into space by clouds and the remaining 19% is absorbed by the atmosphere. The intensity of the sunshine reaching any particular area on the earth varies from zero at sunrise through a noon maximum that may be as high as 300 to 350 BTU per hour per square foot on a cloudless day. Local weather bureau data must be consulted to obtain specific values for any particular locality (see SUN; SUNSHINE).

The total amount of solar energy reaching the earth is about 7×10^{17} kw-hr. per year, more than 30,000 times as much as that used in all man-made devices. This prodigious inflow of energy warms the earth and produces, through photosynthesis, all of the food, fuel, and oxygen upon which life depends.

Though man has sought for many centuries to make direct use of the sun's radiant energy, his success has been meagre, primarily because sunshine is intermittent in availability, variable in direction, and relatively low in intensity. Apparatus intended for use with solar energy must in general be large in area and must be provided with some means for storing energy for use when the sun is not shining. Despite these formidable difficulties, significant advances have been made since 1750 in using solar energy to generate heat, to bring about chemical reactions, and, most recently, to produce usable amounts of electricity.

Early Uses.—Man learned long ago that heat is produced when the sun's rays are absorbed by a blackened surface and that the temperature thus produced could be greatly increased by using reflection or refraction to concentrate a large area of sunshine onto a small target. The concave silver mirrors used by the Incas and the convex quartz lens found in the ruins of Nineveh were probably used to light sacred fires by means of concentrated sunbeams. Archimedes is said to have devised a battery of mirrors to defend Syracuse in 212 B.C. by burning the sails of an invading fleet "at the distance of a bowshot." In 1747 G. L. L. Buffon set up a group of 140 flat mirrors in a Paris garden and ignited a stack of wood placed about 200 ft. from his reflectors, thus demonstrating that the feat attributed to Archimedes might indeed have been accomplished.

A. L. Lavoisier, who experimented with solar energy as early as 1774, was probably the originator of the device known today as the solar furnace. Enclosing specimens of various substances in transparent quartz vessels, he placed them at the focal point of a 52-in. diameter lens and used concentrated solar radiation to heat them in partial vacuum and in controlled atmospheres of oxygen and other gases. He first called attention to one of the principal virtues of the solar furnace when he wrote, "the fire of ordinary furnaces seems less pure than that of the sun."

Modern Applications.—*Heat Production.*—Because of its unique ability to heat materials by intense radiation alone for long periods of time without contamination, the solar furnace has come into prominence as a tool for high-temperature research. Scientists have found that parabolic reflectors taken from antiaircraft searchlights can concentrate solar radiation so effectively that temperatures as high as 3,500° C (6,332° F) can be attained. Equatorial or altazimuth mountings are used to enable the concentrator to follow the apparent motion of the sun across the sky; sleeves or shutters are used to regulate the amount of radiation impinging on the target.

In most of the large solar furnaces the inconvenience caused by target movement is eliminated by using a flat mirror called a heliostat to track the sun across the sky and reflect its rays into a fixed paraboloidal concentrator. The largest furnaces of this type are those at Mont-Louis, France; Sendai, Japan; and Natick, Mass. These furnaces use concentrators that are more than 30 ft. in diameter, made of many small curved glass mirrors arranged approximately in a paraboloidal configuration.

Solar steam generators, built by many pioneers during the 19th century, used arrangements of movable mirrors to concentrate large amounts of solar radiation upon blackened pipes through which water was circulated and turned to steam. Both steam and hot-air engines were operated in this way with some degree of success as early as 1870, and ice was produced in Paris in 1878 in an ammonia-absorption refrigerator operated by a solar boiler. The use of solar energy for pumping irrigation water was tried in Arizona and California, employing a number of solar pumping

stations using conical concentrators 30 ft. in diameter. The largest of all solar-power installations was erected in 1912 on the bank of the Nile at Meadi, near Cairo, using a total of 14,000 sq.ft. of concentrating surface in the form of seven parabolic troughs, each 205 ft. in length. The 100-hp. steam engine connected to this great solar boiler actually produced between 50 and 60 hp. continuously during one five-hour test, but the system was not economically competitive with other pumping apparatus and was abandoned during World War I.

All of these early installations suffered from the same deficiencies—irregularity of operation and excessive cost—and none survived. Interest in solar power revived with the advent of artificial earth satellites, since these applications avoid such earthly problems as clouds, atmospheric absorption, and low-cost competitive energy sources. Serious consideration is again being given to vapour cycles which would receive the full complement of solar radiation, 1.4 kw. per square metre, whenever their collectors turn toward the sun and reject the unused energy by radiation into space.

When heat is needed at moderate temperatures for such purposes as distillation of salt water, growing and drying of agricultural products, cooking, and heating of buildings and domestic hot-water supplies, solar energy can be used with considerable success, thanks to the "greenhouse" effect. Common window glass and many plastic films are able to transmit 90% of the solar radiation that falls on them, but they are relatively opaque to the long waves (8 to 40μ in wave length) emitted by any surface heated to 100°–200° C (212°–392° F). Thus a simple blackened wooden box, covered with several sheets of glass or plastic film, acts as an effective trap for solar energy when it is turned toward the sun. If its sides and bottom are insulated, the internal temperature can be raised as high as 150° C (302° F) by the unaided rays of a bright sun. M. K. Ghosh in India (1945) and M. Telkes in the United States (1955) improved this simple solar stove by adding reflective wings to direct more sunshine into well-insulated ovens, achieving temperatures up to 200° C (392° F).

Production of salt by evaporation of sea water was probably man's first planned use of solar energy. Conversely, the production of potable water from brackish wells or sea water was the first successful large-scale application. A solar still erected in Chile in 1872 used 51,000 sq.ft. of collecting surface and produced some 6,000 gal. of water per day during a period of 40 years. These stills usually employ a shallow blackened box covered with a single layer of glass or plastic film, through which solar radiation enters and evaporates some of the water. The vapour is condensed on the lower surface of the transparent cover and trickles down into channels that lead the condensate into appropriate containers. Since the output of such solar stills is relatively low (approximately 1 gal. per day for each 10 sq.ft. of collection area), they offer little promise for producing irrigation water. They can, however, supply the drinking water requirements for limited numbers of people, and they are being used for this purpose on several of the arid Greek islands, notably at Simi.

Solar water heaters have been in relatively wide use in Florida and the southwestern U.S. for many years. Most of these consist of flat sheets of blackened metal provided with tubes through which water circulates by natural or forced convection whenever the sun is shining. Wastage of the absorbed solar energy is minimized by covering the upper surface of the metal with a glazing of glass or plastic film, separated from the sheet by a small air space. The lower surface is insulated with rock wool, vegetable fibres, or a reflective coating that reduces radiation. Heaters of this type do not have to follow the sun's motion, since they operate effectively if they are mounted in a fixed position facing the south (in the Northern Hemisphere) and tilted so that their angle with the horizontal is equal to the local latitude plus 20°. Temperatures up to 60° C (140° F) can readily be reached on sunny winter days, and the domestic hot-water requirements of a typical family living in regions south of latitude 35° N can be met during most of the year by a heater having as little as 40 sq.ft. of surface.

Similar but much larger collectors can supply most of the heat needed in homes of moderate size in favourable localities. Storage of heat for use at night or during cloudy periods is accomplished by using large insulated tanks to store water heated during daylight hours. This system is particularly effective when radiant heating is used, with the warmed water flowing through tubes in floors and ceilings. Air can also be heated in suitably designed collectors and used in conventional warm-air systems. Heat storage can then be provided by using beds of gravel or containers filled with chemicals (*e.g.*, Glauber's salt) that absorb heat at a suitable temperature when they melt and give off the stored heat when they solidify again.

Solar Power Systems.—Direct conversion of solar radiation into electricity can be accomplished on a small scale in several ways. The thermoelectric effect, first discovered in 1821 and greatly improved during the 1950s by both Russian and U.S. physicists, can be utilized by placing one set of thermocouple junctions in the focal region of a solar furnace while the other set is kept cool. The efficiency of conversion of solar to electric energy was extremely low, less than 1%, when only metallic thermocouple junctions were available. An important advance came with the development of semiconductors, which transmit electricity well but are poor conductors of heat; these give energy conversion efficiencies reportedly as high as 10%. The most efficient and convenient way to convert solar radiation into electricity is through the use of the silicon photovoltaic cells, which were developed in the U.S. in 1954 by the Bell Telephone Laboratories. The Bell solar cell is made of thin wafers of ultrapure silicon to which traces of arsenic and boron are added. In bright sunlight it can produce direct current at 0.6 v. and approximately 0.030 amp. per sq.cm. of exposed cell area, with a conversion efficiency as high as 16%.

Terrestrial solar-power systems have achieved little success because of irregularity of operation and excessive cost. In space, the situation is entirely different, because the supply of solar energy is certain and predictable, and there are no competitive sources of unending energy. The power requirements of transistorized radio and television receivers and transmitters are well within the capability of a moderate area of solar batteries, and their cost, while far too high for earthly applications, is moderate in comparison with their usefulness.

Solar radiation was first used as a source of electricity in space by the U.S. satellite Vanguard I, which was put into orbit on March 17, 1958, carrying 108 silicon solar cells in six groups of 18 cells each. Radiation encountered in the Van Allen belt caused the cells to deteriorate, but in the mid-1960s they continued to

(LEFT) MODULAR FLAT-PLATE ABSORBERS, USED IN HEATING SWIMMING POOLS; (RIGHT) TECHNICIAN ATTACHES SOLAR BATTERIES TO THE SURFACE OF A PROTOTYPE OF THE TELSTAR COMMUNICATIONS SATELLITE

transmit intelligible signals. Subsequent satellites and space vehicles have used much larger numbers of cells arranged in series-parallel circuits so that they could charge sealed storage batteries and thus provide relatively large amounts of power for short periods of transmission. (*See* SPACE EXPLORATION.)

Weather and communications satellites (Tiros, Relay, Telstar) have their outer surface literally covered with thousands of silicon cells, some of which are always facing the sun and generating the power needed to charge their batteries and to operate their radio and television equipment. Space vehicles intended to transmit signals over vast distances employ more than 20,000 cells mounted on panels that can be folded into the launch rocket and then deployed when the desired course has been attained. These vehicles (Ranger, Mariner) are established at such attitudes that their solar panels face the sun continuously.

Future Uses.—To meet the larger power requirements of second-generation space vehicles, thermodynamic power systems that are being developed will use liquid metals as their working fluids, with metallic hydrides for high-temperature heat storage. Very large paraboloidal concentrators have been devised to fit within the narrow confines of a rocket's nose cone and later to unfold or inflate in space. Thermionic converters are also being developed for space applications, since they are apparently relatively immune to radiation damage and can operate at the very high temperatures attained in the focal region of solar concentrators.

Biological systems also under development use sunlit algae to convert exhaled carbon dioxide and water into oxygen and protein-rich carbohydrates. These systems can ultimately be used to sustain astronauts on protracted excursions into space.

The major potential areas of usefulness for terrestrial applications of solar energy lie between 30° N and 30° S latitude, where sunshine is plentiful but conventional energy sources are scarce and fossil fuels expensive. Small solar-powered pumps and refrigerators, still to be developed, would help the billions of people living in these regions to raise their standards of living. Where heat is needed rather than mechanical power or electricity, solar devices are already technologically available, but fuel-burning equipment is still less expensive in most parts of the world.

SOLARI (SOLARIO), **ANDREA** (ANDREA DEL GOBBO) (active 1495–d. 1524), Italian painter of the Milanese school and one of the most important followers of Leonardo da Vinci, was probably born at Milan. He received his early training from his brother Cristofano, a distinguished sculptor and architect, who was employed extensively on work at the cathedral at Milan and at the Certosa di Pavia. He probably accompanied his brother to Venice, where he seems to have been strongly influenced by Antonello da Messina, who was then active in the city. The fine portrait of a man with a pink (National gallery, London) displays Antonello's plastic conception of form and was probably painted about 1492. Solari's earliest dated work is a "Holy Family and St. Jerome" (Brera, Milan), with a fine landscape background, executed for S. Pietro at Murano in 1495. The Leonardesque type of the Madonna proves that Solari after his return from Venice became strongly influenced by the great Florentine artist, who was then carrying everything before him. To this period belong a small "Crucifixion" (1503, Louvre, Paris); the portrait of Charles of Amboise (Louvre); the portrait of Longono (1505, National gallery, London); "The Annunciation" (1506, Fitzwilliam museum, Cambridge); the beautiful "Virgin on a Green Cushion" (Louvre), for which a sensitive drawing of the Virgin's head is in the Ambrosiana at Milan; and the "Head of the Baptist in a Silver Charger" (1507, Louvre). In 1507 Solari went to France with letters of introduction to the cardinal of Amboise and was employed for two years on frescoes in the chapel of his castle of Gaillon in Normandy (demolished during the French Revolution). It has been suggested that Solari may have visited Flanders before returning to his native country, and this may account for the Flemish character of his later work. In 1515 he painted the "Flight Into Egypt" (Poldi-Pezzoli, Milan), with its harmonious and detailed landscape background. To this period belong the "Procession to Calvary" (Borghese gallery, Rome); the portrait of the chancellor Domenico Morone (Palazzo Scotti, Milan); and the "Woman Playing a Guitar" (Hertz collection, Rome). Solari's last work was an altarpiece representing "The Assumption of the Virgin," left unfinished at his death and completed by Bernardino Campi about 1576. Solari died between Aug. 18 and Oct. 7, 1524.

SOLAR SYSTEM consists of the sun and the complex assemblage of bodies revolving around it in closed orbits under the dominating influence of its gravitational attraction. For a detailed discussion of the various members of the solar system *see* SUN; PLANETS; COMET; METEOR; METEORITES; MOON; and the planets under their individual names (*see* below). Only a brief survey of the solar system as a whole is given here.

The solar system is usually defined as extending to the orbit of the outermost known planet, Pluto, 40 astronomical units from the sun. (The astronomical unit is equal to the semi-major axis of the earth's orbit, 93,000,000 mi. in length.) If the solar system is considered to extend to the aphelia of the comets with nearly parabolic orbits, however, its extent is much larger—approximately 100,000 astronomical units. More than 99% of the mass of the solar system is in the sun. The rest of the solar system consists of empty space traversed at wide intervals by bodies of relatively insignificant mass. These bodies may be grouped into two solar families: (1) the 9 major planets, with 31 satellites attending 6 of them, and the 1,600 known asteroids; and (2) about 1,000 comets, a horde of meteors and meteorites, and a thin cloud of interplanetary dust. These are the known members of the solar system. It has been estimated that there are 40,000 asteroids bright enough to be photographed with a 100-in. telescope. A long search with a large telescope would probably reveal more satellites, especially of the giant planets. New comets are discovered at the rate of half a dozen per year on the average. But it is very doubtful if any unknown distant major planets brighter than the 16th magnitude exist.

The Sun.—The sun is the only star close enough so that its surface can be viewed from the earth. All other stars are so distant that they appear merely as points of light in the largest telescopes. In a sense we may be in actual contact with the sun at times, for there is evidence that the earth is occasionally enveloped in particles emitted by the solar surface. Compared with the average star, the sun is slightly more luminous, slightly larger and more massive, and slightly less dense. It is 109 times the diameter of the earth and 333,000 times as massive. The temperature at the surface of the sun is 6,000° K and is believed to increase to perhaps 14,000,000° K at the centre. Although the density of material near the centre of the sun is eight times the density of lead, it is gaseous throughout.

The sun radiates at the rate of 9×10^{25} cal. per sec., emitting enough energy to melt a 3,000-ft. layer of ice surrounding it in 90 min. This energy is derived from thermonuclear processes involving the transformation of hydrogen into helium. Although the sun loses 4,000,000 tons of hydrogen per second in this process, it is believed that the sun will continue to radiate at essentially its present rate for hundreds of millions of years.

The bright surface of the sun that is seen from the earth is called the photosphere. Above the photosphere is a region called the chromosphere. During a total solar eclipse, when the light of the photosphere is completely covered by the moon, the chromosphere appears as a brilliant scarlet ring surrounding the sun. Often ruby-coloured clouds or prominences may also be seen at the edge of the sun. The most spectacular sight is the halo of pearly white light or corona that flashes out around the sun during the total phase of an eclipse. The spectrum of the corona shows bright lines that have been identified with lines emitted by atoms of iron, nickel, and calcium ionized from 9 to 15 times.

The high level of ionization in the corona indicates a temperature of about 1,000,000° K. With special instruments it is possible

to make certain observations of the prominences, chromosphere, and even the corona without waiting for a total eclipse.

The most conspicuous markings visible directly on the disk of the sun with only a small telescope are the groups of dark spots (sunspots). They range in size from mere specks a few hundred miles in diameter to areas 30 times the equatorial cross section of the earth. These large spot groups can be seen by the unaided eye when suitably protected by dark glasses. (A telescope should never be pointed at the sun without using proper filters.) The spots appear dark only by contrast with the hotter photosphere around them, being at a temperature of about 4,500° K. The number of spot groups increases and decreases at irregular intervals that average 11 yr. in length.

The Major Planets.—The major planets in order of increasing distance from the sun are Mercury, Venus, Earth, Mars, Jupiter, Saturn, Uranus, Neptune, and Pluto. These may be divided into the terrestrial planets, Mercury, Venus, Earth, and Mars, nearest the sun; and the giant planets, Jupiter, Saturn, Uranus, and Neptune, beyond them. Pluto is believed to be about 0.45 the size of the earth but is beyond the orbit of Neptune. There are reasons for believing that Pluto may once have been a satellite of Neptune, which escaped from its gravitational control. The terrestrial planets are of about the same size and mass as the earth and of high density. The giant planets have from 15 to 318 times the volume of the earth but have only about 20% the density of the terrestrial planets. The high density of the terrestrial planets is attributed to their large metallic content. The giant planets are believed to consist mostly of the lightest elements, hydrogen and helium, which are probably found deep in the interior of the planets in a solid or possibly even metallic state.

The Asteroids or Minor Planets.—The orbits of more than 1,600 asteroids have been computed since the discovery of the first one in 1801. The size of these minor planets ranges from about 500 mi. in diameter to one mile or less. Their total mass is estimated at only 1/3,000th that of the earth. Almost all of the asteroids revolve between the orbits of Mars and Jupiter. But a few exceptional ones have elongated orbits that extend from Mercury to Mars, in the case of Icarus, and from Mars to Saturn, in the case of Hidalgo. Some of the exceptional asteroids, such as Hermes and Eros, have come within a few million miles of the earth.

Natural Satellites.—A satellite is defined as a body which revolves around a planet. It is thus distinguished from a planet by its motion rather than by any physical property. Mercury, Venus, and Pluto have no known satellites, the Earth has 1, Mars has 2, Jupiter has 12, Saturn has 9, Uranus has 5, and Neptune has 2. Some satellites are only a few miles in diameter, as in the case of the two tiny moons of Mars and the outer satellites of Jupiter. A few satellites are about the size of Mercury and Mars, as in the case of Ganymede and Callisto of Jupiter, Titan of Saturn, and Triton of Neptune, which are each about 3,500 mi. in diameter.

Comets.—Comets are bodies of great size but small mass. They are popularly pictured as bright stars flashing erratically across the sky followed by long luminous tails. But very few comets become bright enough to be seen without a telescope, and their motions are not erratic but, as with the planets, in accordance with the law of gravitation. Apparent slight deviations from gravitational motion observed in the case of a few comets like Encke's may be due to the action of internal forces within the comet's nucleus.

In contrast to the nearly circular orbits in which the planets and most of the asteroids move, most comets revolve in greatly elongated orbits. Cometary orbits may also be inclined at any angle to the ecliptic. The comets of short period, less than 100 yr., move in orbits of moderate inclination. Halley's comet is the only periodic comet that moves in a retrograde direction. A few comets revolve in nearly circular orbits.

Meteors and Meteorites.—A meteor or "shooting star" refers both to the flashes of light occasionally seen darting across the night sky and to the objects that produce the light. Meteors may be no larger than a grain of sand or a pea. The glow is produced by collisions between the atoms of the meteor and the molecules of the air. Such meteors are consumed in the atmosphere at altitudes of about 60 mi. Some meteors, having a mass of a few ounces to many tons, survive their rush through the atmosphere and reach the earth. They are called meteorites. Micrometeorites a few microns in diameter sift through the atmosphere and reach the earth as dust particles.

When the earth encounters a swarm of meteors moving in an orbit around the sun, there occurs a meteor "shower," during which the number of meteors counted per hour may amount to several dozen or more. Very seldom does a display resembling a real shower occur. But there have been a few times when meteors appeared to stream from the sky as thickly as snowflakes. The orbital elements of some meteor swarms are so similar to those of certain comets that there can be no doubt that they are identical. The meteoric material evidently originates from debris left behind by the disintegration of the comets.

Interplanetary Dust.—Under favourable conditions a wedge-shaped glow may sometimes be seen along the ecliptic extending upward from the western horizon after sunset or from the eastern horizon before sunrise. This is the zodiacal light which apparently originates from a swarm of dust particles surrounding the sun in the plane of the earth's orbit or ecliptic and extends out to the orbit of the earth and beyond. The total quantity of dust must be very small, as it does not noticeably interfere with the motion of the inner planets.

Another phenomenon attributed to dust or meteorites is the gegenschein or "counterglow," which may sometimes be seen as a faint hazy patch of light in the night sky always directly opposite the sun. It is variously attributed to light reflected from meteorites or dust trapped by dynamic or electrical forces opposite the earth from the sun.

Regularities in the Solar System.—The nine major planets revolve around the sun in the direction customarily referred to as direct. They move in elliptic orbits that depart only slightly from circles. These orbits lie nearly in the plane of the earth's orbit, which is used as a reference plane. Except for the orbit of Pluto, which has a tilt of 17°, no other planet has a tilt to this plane greater than 7°. The sun also rotates on its axis in the same direction that the planets revolve around it. The earth's moon, the 2 satellites of Mars, 8 of the 12 satellites of Jupiter, and 8 of the 9 satellites of Saturn revolve around their planets in this same direction. But four of the small satellites of Jupiter and the outermost satellite of Saturn revolve in a retrograde direction. These tiny bodies may be captured asteroids. However, this explanation is not so plausible in the case of a large satellite of Neptune that also revolves in the retrograde direction.

All of the 1,600 asteroids revolve around the sun in the same direction as the planets and in about the same plane. Most of the asteroids also move in nearly circular orbits. As already noted, there are a few exceptional asteroids that move in elongated orbits like most of the comets. But there are also several comets that move in nearly circular orbits like the majority of the asteroids.

Theories of the Origin of the Solar System.—The orderly arrangement and motion of the planets and asteroids are impressive evidence that they form a true solar system. It seems impossible that such a system could have resulted from chance encounters between these hundreds of bodies. Another significant factor is the extreme isolation of the solar system. The nearest star is 60,000 times as far away as the outermost planet, Pluto. The evidence is thus overwhelming that the members of the solar system had a common origin. Theories of the origin of the solar system have been of two general types: (1) origin by an orderly process of evolution; and (2) origin by catastrophe.

The classic example of the first type is the nebular hypothesis advanced by the French mathematician Pierre Laplace in 1796. He postulated a vast discus-shaped mass of cold gas in slow rotation extending beyond the orbit of the farthest planet. As this nebula contracted under the mutual gravitation of its parts, its rate of rotation necessarily increased to conserve angular momentum. The angular momentum of a body rotating around a centre is the product of its mass, velocity, and the radius connecting it

with the centre. It can be proven that the angular momentum of a closed system cannot change. If, for example, the radius decreases the velocity increases proportionately so that the product remains the same. Eventually the rate of rotation increased so much that the centrifugal force at the periphery of the nebula exceeded gravitation, causing a ring of material to separate from the main mass. As contraction continued, other rings broke off at successively smaller distances from the centre.

These rings were not of uniform width all the way around. The densest portion gradually drew material to it and condensed into a planet. The satellites were formed by condensation from the contracting planets. The comets and meteors were presumably formed from material left over between the planets. Today the sun is all that remains of the primeval nebular mass.

Laplace's nebular hypothesis was one of the most successful theories in the history of science. For a century it was practically unchallenged. About 1900, however, it encountered criticism which caused it to be discarded. The chief objection to the nebular hypothesis is the peculiar distribution of angular momentum found in the solar system. The planets, which possess less than 1% of the mass of the solar system, by some means have been able to acquire 98% of its angular momentum. Scientists cannot conceive of a natural physical process during which the angular momentum of a system could have been so unequally distributed. Also it is more likely that matter would have separated from the nebula particle by particle rather than in the form of a ring.

One way to get a large amount of angular momentum into the planets is to put it there. This could be done by having the necessary energy forcibly injected from outside the system. Under this theory of catastrophe it is assumed that the sun suffered a collision or near-collision with a passing star. As the star approached, great tides were raised on the sun. If the star came close enough, there was not merely a tidal bulge but an ejection of matter from the sun in the form of a long filament. The end of the filament tended to follow the star into space, causing it to move in a curved direction around the sun. Some of the material also fell back on the sun and started it rotating in the same direction as the revolution of the filament around it. According to this theory, the filament broke into separate parts which ultimately condensed into the planets. Again the asteroids, comets, and meteorites consist of debris left over between the planets.

This theory sounds fairly plausible, but calculations indicate that the ejected filament, instead of revolving around the sun, would probably have followed along behind the passing star into outer space. To meet this objection the theory has been modified by assuming that the sun was originally a double star and that the collision was with the sun's companion. The colliding stars could have gone off in different directions leaving the central part of the filament torn from them nearly motionless near the sun. But highly heated material dragged from the interior of a star would be more likely to explode, forming a thin atmosphere around the sun, than to condense into planets. However, the most serious objection to any encounter theory is the great distance between the stars. The probability that two stars will collide is practically nil. In an attempt to circumvent this difficulty it has been assumed that the filament was formed when a companion of the sun exploded and became a nova.

Modern theories of the origin of the solar system generally reject catastrophic processes and prefer as their starting point a primeval mass of cold gas, as in the old nebular hypothesis. There would be considerable turbulence in such a large mass, with currents forming and dying down and forming again. Eventually this mass would break up into gas clouds or protoplanets. The material at this time would have been cold, but eventually, with contraction, the central mass would have become hot enough to radiate. This radiation would have caused the planets to lose much of their mass into space by evaporation. In this way the difficulty in connection with angular momentum is avoided.

It should be emphasized that no theory of the origin of the solar system has as yet won general acceptance. All involve highly improbable assumptions. But the difficulty is in trying to find a theory with any degree of probability at all.

Is the Solar System Unique?—With our largest telescopes we cannot hope to detect a planet even as large as Jupiter revolving around the nearest stars. Hence we have no direct knowledge of any stellar planetary systems. But we know that stellar associations are common in the Milky Way. Probably more than half of the "stars" are actually binaries or systems of higher multiplicity. We know of stars with companions only 0.016 as massive as the sun, or 17 times the mass of Jupiter. It seems reasonable to suppose, therefore, that many stars are accompanied by bodies of planetary dimensions.

See also references under "Solar System" in the Index.

(R. S. Rn.)

SOLDERING. Soldering and brazing are processes for joining metals by the application of heat. A common characteristic of both processes is the use of a filler metal that melts and wets the surfaces of the joint at temperatures below the melting points of the metals being joined. The distinguishing difference between the processes is the strength of the joint and the temperature required for making it.

The soldering process relates only to joints made below 800° F (about 430° C) with solders melting well below this temperature (formerly called the soft solders). The major requirement is sealing and solidifying the assembly and the minor requirement is high joint strength. Fabrication at low temperatures is often the easiest and most convenient method of joining to avoid destruction of heat-sensitive materials surrounding the joint.

The brazing process relates to joints made with brazing filler metals (hard solders) at temperatures in the range of 1,100° to 2,150° F (595° to 1,175° C). Brazed joints are stronger than soldered joints. Brazing is sometimes classified as a welding process, although the latter usually implies fusion of the metals being joined.

Solder Alloys.—Solders of the tin-lead alloy system constitute the largest portion of all solders in use. Alloys containing from 5 to 70% tin, with the balance lead, are available in a melting range of 361° to 594° F (183° to 312° C). They are used for joining copper, brass, nickel-silver, iron, tinplate, and other coated metals. For special purposes, tin-antimony, tin-antimony-lead tin-zinc, tin-silver, and lead-tin-silver solders are used. Special low melting alloys, melting below 300° F contain bismuth cadmium, tin, and lead (*see* also FUSIBLE ALLOYS). The composition melting characteristics, and applications of the commonly used solders are given in Table I. The melting characteristics of the various alloys are indicated in terms of their solidus, or temperature below which the alloy is completely solid, and their liquidus above which it is completely molten (*see* METALLOGRAPHY: *Metal and Alloy Structure*).

form with rosin or zinc chloride (acid) cores. Paste solders consist of powdered solder mixed with flux. This is a convenient method of applying a controlled amount of flux.

Brazing Filler Metals.—The choice of brazing filler metal depends on the base metals and service requirements of the brazed part. The composition, melting characteristics, and applications for brazing filler metals are given in Table II. Brazing filler metals are classified into six main groups.

Brazing Process.—Preparation of the surfaces by mechanical or chemical cleaning is important. The extensive use of silver-based brazing alloys melting at temperatures below 1,200° F (650° C) required development of fluxes that are fluid and active at 1,100° F. Combinations of borates, fluoborates, fluorides, chlorides, borax, and boric acid are commonly used as fluxes.

Brazing filler metals are free flowing when heated to the proper temperature. Proper attention must be given to design and alignment. In most applications (fig. 2) joint clearances should be in the order of 0.002 to 0.005 in. (0.005 to 0.013 cm.) except

Soldering Process.—Typical designs for soldered joints are illustrated in fig. 1. The basic steps in making a joint are: (1) The joining surfaces are thoroughly cleaned by mechanical or chemical means. (2) A soldering flux is applied to remove oxide films, promote wetting, and prevent reoxidation of the surfaces during heating. (3) The joint is aligned to provide a clearance of 0.001 to 0.005 in. (0.003 to 0.013 cm.) and to promote capillary flow. (4) Heat is applied with a soldering iron or torch. Induction, resistance, or oven heating, and dip soldering are other methods of applying heat. (5) Solder is hand-fed or preplaced in the joint as a preform. (6) The joint is cooled without movement. (7) Corrosive flux residues are removed.

In a technique developed for assembling microminiature electronic components, a small globule of solder is melted on the tip of a soldering iron; when the joint is touched to the globule, solder flows up and around it, heating it only to the melting point of the solder, or substantially below the temperatures required for conventional hand or dip soldering.

Fluxes.—Soldering fluxes are available commercially for any soldering application. A quick acting corrosive flux is a water solution of three parts zinc chloride and one part ammonium chloride. Hydrochloric acid or stannous chloride, or both, are added to zinc chloride fluxes for soldering stainless steels. An alcoholic solution of rosin is noncorrosive but slower acting. Rosin fluxes are used for soldering electronic equipment, easily solderable metals, and metals that have been precoated with a solderable coating. The lead-tin alloys can be supplied in tubular

TABLE II

BRAZING FILLER METALS

FIG. 2.—TYPICAL JOINTS FOR BRAZING

in the case of aluminum where clearances of 0.006 to 0.025 in. (0.015 to 0.064 cm.) are used. Capillary forces play an important part in distributing the alloy. The alloys may be preplaced or fed into the joint by hand.

Heating for brazing is done with torches, inductive heating, electrical resistance, molten salts, and baths of molten metal. The wide use of these processes has led to the development of special furnaces and automatic equipment with special attention being given to accurate control of the temperature and regulation of the atmosphere. Jigs and fixtures are necessary for dip brazing.

Brazing fluxes are highly corrosive and the residue that remains in the joint area must be removed. Some flux residues are soluble in hot water. In stubborn cases it may be necessary to use warm 10% sulfuric acid followed by hot water.

The soldering and brazing manuals of the American Welding Society are comprehensive sources of information on soldering and brazing. (R. M. MacI.)

SOLENOIDS, ATMOSPHERIC: *see* Baroclinic.

SOLENT, THE, a strait of the English Channel, between the mainland (the coast of Hampshire, Eng.) and the coast of the Isle of Wight. It is the submerged valley of an eastward-flowing river of which the present Frome was the headstream and the Itchen and Test, two tributaries. Spithead, the drowned eastern portion of the same valley, is on the whole wider than the western part, and therefore affords a safer approach to Southampton for very large craft. From Southampton Water to the Needles is 15 mi., (24 km.) and from Southampton Water to Spithead about half the distance; the breadth is from 1¼ to 4 mi. (3 to 6 km.). Opposite the Needles there springs from the mainland a great pebbly bank, nearly 2 mi. in length, on the end of which stands Hurst Castle, dating from the time of Henry VIII. At the mouth of Southampton Water another pebbly bar, projecting from the western shore, also bears a Tudor fortress, Calshot Castle. The low coast of the mainland is broken by the estuaries of the Beaulieu River and the Lym; the coast of Wight, which rises more steeply, is cut by the Medina, Newton, and Yar estuaries. The Solent is frequently the scene of yacht races, especially from Cowes, and also of naval reviews, off Spithead.

SOLER, ANTONIO (1729–1783), the most important Spanish instrumental and church music composer of the later 18th century. Born at Olot de Porrera, Gerona, on Dec. 3, 1729, he was educated in the choir school of Montserrat and at an early age was appointed *maestro de capilla* at Lérida Cathedral. In 1752 he joined the order of St. Jerome (Hieronymites), and in the same year became organist at the Escorial monastery, near Madrid. Later he was a pupil of Domenico Scarlatti, then in residence at the Spanish court, and he himself taught members of the royal family. Scarlatti's influence may be perceived in the lively keyboard technique, the form, and the often unexpected harmonic progressions of his numerous harpsichord sonatas. Besides these he wrote much church music, in which he indulged a taste for intricate canons; incidental music for plays by Calderón and others; six quintets for organ and strings; and six concertos for two organs. He was also the author of a theoretical treatise, much discussed by his contemporaries, entitled *Llave de la modulación* (Madrid, 1762), and experimented in microtones, inventing for the purpose a keyboard instrument called the *afinador*. He died at the Escorial, on Dec. 20, 1783.

See F. M. Carroll, *An Introduction to Antonio Soler* (1960). (L. Sa.)

SOLESMES, French village on the Sarthe River in the *département* of Sarthe, 29 mi. (47 km.) WSW of Le Mans by road, is well known for its abbey, the mother house of the French Benedictines. Pop. (1962) 489. Founded at Solesmes in 1010, the monastery was reformed by the Maurists (1664), suppressed at the Revolution (1791), and refounded by P. L. P. Guéranger (*q.v.*), under whom it became an abbey (1837) and the centre of the reform of plainsong (*q.v.*). Expelled from France in 1901, the monks built Quarr Abbey, Isle of Wight, England. They returned to Solesmes in 1922. The church (11th–16th centuries) contains fine Renaissance sculptures. *See* also Benedictines: *The Reformation and After.* (P. J. G.)

SOLI, an ancient seaport of Asia Minor, situated at the western end of the Cilician plain, about 5 mi. (8 km.) W of modern Mersin, the older parts of which were largely built from the ruins of Soli. It was founded by colonists from Rhodes and was so prosperous when taken by Alexander the Great (333 B.C.) that he was able to exact from it a fine of 200 talents for its attachment to Persia. It was destroyed and depopulated by Tigranes of Armenia but revived by Pompey, who settled the defeated Cilician pirates there and renamed it Pompeiopolis. The bad Greek spoken there gave origin to the term solecism (Greek *soloikismos*). The remains of the artificial harbour, slightly awash, can be traced in the form of two parallel moles with curving ends. The most striking remains in the city are the relics of a long colonnade which flanked its main highway, leading to the harbour. (Wm. C. B.)

SOLI (Greek Soloi), an ancient Greek city of Cyprus, just west of modern Karavostasi on Morphou Bay. It was believed to have been founded after the Trojan War by the Attic hero Acamas. According to another tradition it took its name from the Athenian lawgiver Solon, who was supposed to have visited Cyprus. Soli is probably the town Sillu, whose king Irisu was an ally of Esarhaddon of Assyria in 672 B.C. In Hellenic times Soli had little political importance, though it stood a siege from the Persians *c.* 497 B.C.; its copper mines, however, were famous, and a neighbouring monastery is dedicated to "Our Lady of the Slag Heaps" (Panagia Skouriotissa). Excavated monuments include a theatre, a temple of Aphrodite and Isis, and a 5th-century palace situated 5 mi. W of the town at Vouni.

See E. Gjerstad and A. Westholm in *The Swedish Cyprus Expedition*, vol. iii, pp. 76–582 (1937).

SOLICITOR: *see* Legal Profession.

SOLIDS, GEOMETRIC, are portions of space that correspond to physical solids (*e.g.*, spheres, cubes, pyramids). If a surface separates three-dimensional space into two regions, one of which is finite, the other is, of course, infinite. The finite region is called the interior of the surface. The surface plus its interior is called a solid; the surface itself is called the boundary of the solid (*see* Surfaces). From the standpoint of topology, such surfaces, being closed and orientable, fall into a sequence of families such that any two surfaces belonging to the same family are homeomorphic; *i.e.*, each can be distorted or stretched into the other by a continuous point-to-point transformation. (For example, a cube of clay can be distorted by squeezing to form a sphere.) Each family is characterized by a nonnegative integer called the genus. A sphere has genus zero, and a surface of genus k is homeomorphic to a sphere with k handles. (Physically, a handle would be represented by a half-doughnut with both cut ends pasted to the spherical surface.) The case $k = 1$ is a ring or torus (*see* Topology, Algebraic; Topology, General).

A solid is said to be convex if it contains the whole of the segment joining each pair of its points. The boundary of a convex solid is called a convex surface. Every convex surface has genus zero; but a sphere (*q.v.*) can easily be distorted to lose its convexity without changing its genus. (For instance, a ball of clay can be molded to make a bowl, in which case many segments that connect pairs of points pass through the concave depression rather than through the solid clay itself.)

Any solid has a convex hull: the unique smallest convex solid that contains it. Similarly, any solid has a circumsphere: the unique smallest sphere that contains it; the radii of circumspheres for some geometric solids are given in the Table.

Let C denote the volume of a solid, and A the surface area of its boundary. Then the ratio A^3/C^2 has the value $36\pi(= 113.09 \ldots)$ for a sphere (of any radius) and a greater value for any other shape; *e.g.*, it is 216 for a cube (*q.v.*). Thus, of all solids with a given volume, the sphere has the smallest surface; and of all solids with a given surface, the sphere has the greatest volume. (*See* also MENSURATION.)

Any solid can be approximated as closely as desired by a polyhedral solid, whose boundary is a polyhedron.

Polyhedrons.—A polyhedron is a finite set of plane polygons so arranged that every side of each polygon (*q.v.*) belongs to just one other, and no two adjacent polygons lie in the same plane (with the restriction that no subset has the same property). The polygons and their sides and vertices are called faces, edges, and vertices of the polyhedron; their numbers are conveniently denoted by F, E, and V. For instance, the cube has $F = 6$, $E = 12$, and $V = 8$. Every convex polyhedron satisfies Euler's formula

$$V - E + F = 2$$

Conversely, every Eulerian polyhedron (*i.e.*, every polyhedron for which $V - E + F = 2$) is homeomorphic to a convex polyhedron. More generally, a polyhedron of genus k satisfies

$$V - E + F = 2 - 2k$$

Fig. 1 shows one for which $V = F = 16$ and $E = 32$, so that $k = 1$. The simplest polyhedron is the tetrahedron (or triangular pyramid) for which $V = F = 4$ and $E = 6$ (*see* PYRAMID).

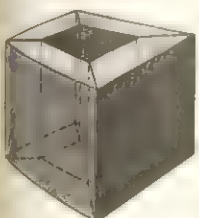

FIG. 1.—POLYHEDRON OF GENUS ONE

Since at least three edges meet at a vertex, $V \leqq 2E/3$; similarly $F \leqq 2E/3$. There is no polyhedron with exactly 7 edges; for $E = 7$ would make both V and F less than 14/3 (that is, $V = F = 4$) and this would leave a tetrahedron (for which $E = 6$, not 7).

Concern here is with polyhedrons that can bound solids, and no mention has been made of nonorientable (or one-sided) polyhedrons. For such a polyhedron, the Euler-Poincaré characteristic $V - E + F$ may take any one of the values $1, 0, -1, -2, \ldots$.

Uniform Polyhedrons.—A polyhedron is said to be uniform if all its faces are regular polygons while all its vertices are alike. The latter requirement means that, for any edge AB, it is possible to transform A into B by a rotation or reflection that transforms the whole polyhedron into itself. A uniform polyhedron is said to be regular if its faces are all alike. The five regular solids (fig. 2) are all mentioned in Plato's *Theaetetus* and are described in detail in the last books of Euclid's *Elements*.

Each uniform polyhedron can be characterized by indicating the number of edges for each of the faces that come together at a vertex (in their proper cyclic order). In this notation the cube is 4.4.4 (since three 4-edged faces meet at each vertex), the uniform n-gonal prism (*q.v.*) is $4.4.n$, and the uniform n-gonal antiprism (or prismoid) is $3.3.3.n$. The only convex uniform polyhedrons are the five Platonic solids, the prisms and antiprisms, and the 13 so-called Archimedean solids. These are listed in the Table with the names that Johannes Kepler gave them in 1619. In the F column, the faces of different kinds are given separately; *e.g.*, in the case of the icosidodecahedron 3.5.3.5, the entry $20 + 12$ means that the faces consist of 20 triangles and 12 pentagons.

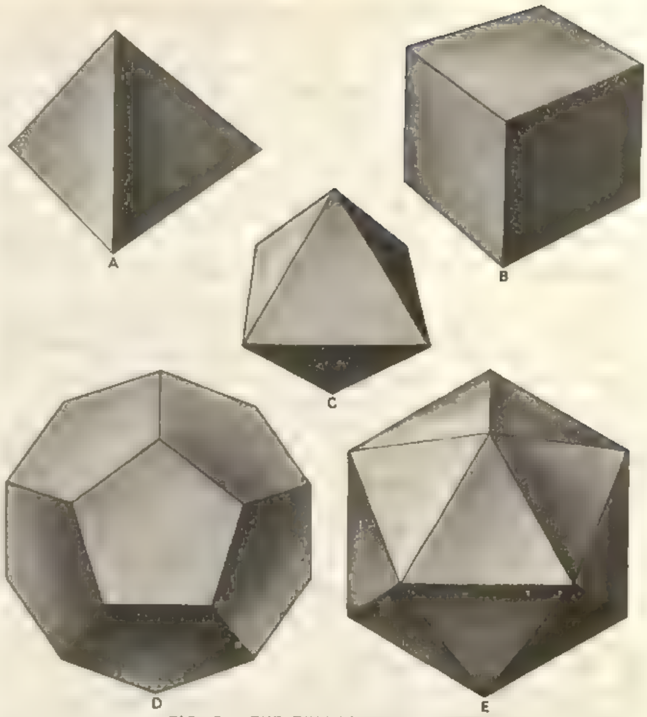

FIG. 2.—THE FIVE PLATONIC SOLIDS

(A) Tetrahedron; (B) cube (hexahedron); (C) octahedron; (D) dodecahedron; (E) icosahedron

The truncated cube 3.8.8 is derived from a solid cube by cutting off the 8 corners to leave 8 triangles, while the 6 squares become 6 octagons. Truncating more deeply, so that the squares are reduced to smaller squares (with one vertex on each original edge), gives the cuboctahedron, so called because, instead of being derived from a cube, it could just as easily have been derived from an octahedron. The cuboctahedron itself can be truncated; but its 12 corners yield 12 rectangles. Kepler's truncated cuboctahedron is derived by distorting these rectangles into squares. (For this reason, its name was changed in earlier editions of *Encyclopædia Britannica* to great rhombicuboctahedron.) Truncating more deeply, and then applying the same kind of distortion, produces the rhombicuboctahedron (or small rhombicuboctahedron). The snub cube (Kepler's *cubus simus*, which could more logically have been named snub cuboctahedron) is derived from the truncated cuboctahedron by first selecting half the vertices so that every edge joins a selected vertex to a rejected vertex, and then performing another slight distortion. The 24 selected vertices belong to a solid bounded by 24 scalene triangles (one for each rejected vertex), 8 equilateral triangles (one inscribed in each hexagon), and 6 squares (one inscribed in each octagon); thus the entry under F in the Table reads $(24 + 8) + 6$ for the snub cube. The distortion is needed to make the scalene triangles equilateral.

The remaining Archimedean polyhedrons (including the snub dodecahedron, which could more logically have been named snub icosidodecahedron) can be derived in a corresponding manner from the other Platonic solids.

Any maker of models (*see* MATHEMATICAL MODELS) can observe that the amount $\delta°$ by which the sum of the face angles at a vertex falls short of 360° is smaller for a complicated solid like the truncated icosidodecahedron than for a simple one like the tetrahedron. René Descartes (*q.v.*) showed that if δ is the same at every vertex, the number of vertexes is $720/\delta$. For instance, in the case of 4.6.10, the face angles at a vertex are 90°, 120°, 144°; therefore $\delta = 6$ and $V = 120$.

In many ways polyhedrons play the same role in space as polygons in the plane. But the theory of dissection provides a remarkable contrast. Any polygonal region can be dissected into a finite number of triangular pieces that can be reassembled to form any other polygon having the same area. But it was discovered by

Table of Uniform Polyhedrons

	Name	Face characteristics at each vertex	V	E	F	Circumradius for edge 2 (or circumdiameter for edge 1)
Platonic	Tetrahedron	3.3.3	4	6	4	$\sqrt{3/2}$
	Cube (Hexahedron)	4.4.4	8	12	6	$\sqrt{3}$
	Octahedron	3.3.3.3	6	12	8	$\sqrt{2}$
	Dodecahedron	5.5.5	20	30	12	$(\sqrt{5}+1)\sqrt{3}/2$
	Icosahedron	3.3.3.3.3	12	30	20	$\sqrt{(5+\sqrt{5})/2}$
	Prism	4.4.n	$2n$	$3n$	$n+2$	$\sqrt{1+\operatorname{cosec}^2\pi/n}$
	Antiprism	3.3.3.n	$2n$	$4n$	$2n+2$	$\sqrt{1+\frac{1}{4}\operatorname{cosec}^2\pi/2n}$
Archimedean	Cuboctahedron	3.4.3.4	12	24	$8+6$	2
	Icosidodecahedron	3.5.3.5	30	60	$20+12$	$\sqrt{5}+1$
	Rhombicuboctahedron	3.4.4.4	24	48	$8+(12+6)$	$\sqrt{5+2\sqrt{2}}$
	Rhombicosidodecahedron	3.4.5.4	60	120	$20+30+12$	$\sqrt{11+4\sqrt{5}}$
	Truncated tetrahedron	3.6.6	12	18	$4+4$	$\sqrt{11/2}$
	Trucated cube	3,8,8	24	36	$8+6$	$\sqrt{7+4\sqrt{2}}$
	Truncated octahedron	4.6.6	24	36	$6+8$	$\sqrt{10}$
	Truncated dodecahedron	3.10.10	60	90	$20+12$	$\sqrt{(37+15\sqrt{5})/2}$
	Truncated icosahedron	5.6.6	60	90	$12+20$	$\sqrt{(29+9\sqrt{5})/2}$
	Truncated cuboctahedron	4.6.8	48	72	$12+8+6$	$\sqrt{13+6\sqrt{2}}$
	Truncated icosidodecahedron	4.6.10	120	180	$30+20+12$	$\sqrt{31+12\sqrt{5}}$
	Snub cube	3.3.3.3.4	24	60	$(24+8)+6$	2.6874267 . . .
	Snub dodecahedron	3.3.3.3.5	60	150	$(60+20)+12$	4.3116747 . . .

Max W. Dehn that there is no finite number of tetrahedral pieces into which a solid cube can be dissected to make a solid regular tetrahedron.

Reciprocal Polyhedrons.—The clumsy symbol 3.3.3.3.3 for the icosahedron may be replaced by the Schläfli symbol $\{3,5\}$, indicating that five 3-edged faces meet at each vertex. In this notation the remaining Platonic solids are characterized as follows: tetrahedron $\{3,3\}$, octahedron $\{3,4\}$, cube $\{4,3\}$, and dodecahedron $\{5,3\}$. Properties of any Platonic solid may be expressed in terms of the general Schläfli symbol $\{p,q\}$; for instance, the total number of edges E for the solid is given by

$$\frac{1}{E} = \frac{1}{p} + \frac{1}{q} - \frac{1}{2}$$

Thus for the cube ($p = 4$; $q = 3$) the value of $\frac{1}{E}$ is found to be $\frac{1}{4}+\frac{1}{3}-\frac{1}{2}=\frac{1}{12}$; showing a total of 12 edges for that solid.

Two polyhedrons are said to be reciprocal (*see* DUALITY) if their vertices, edges, and faces can be paired to make any two vertices that terminate an edge of one polyhedron correspond to two faces that share an edge of the other, and vice versa. In particular, $\{p,q\}$ and $\{q,p\}$ are reciprocal; the centres of the faces of polyhedron $\{p,q\}$ are the vertices of an inscribed $\{q,p\}$. Then the sphere inscribed in the former is the circumsphere of the latter.

More symmetrically, a smaller $\{p,q\}$ and a larger $\{q,p\}$ may be combined so that every edge of each perpendicularly bisects the corresponding edge of the other. Then both solids have the same midsphere; *i.e.*, the same sphere touches all their edges. Such a combination of two reciprocal tetrahedrons $\{3,3\}$ occurs in nature as a crystal twin. Kepler called it *stella octangula;* the 12 edges of the two tetrahedrons are the diagonals of the 6 faces of a cube, which is the convex hull of the twin (*see* also DIAMOND: *Crystallography*). Similarly, a cube $\{4,3\}$ and an octahedron $\{3,4\}$ with crossing edges form a combination whose convex hull (the rhombic dodecahedron) is the reciprocal of the cuboctahedron. The analogous icosahedron-dodecahedron combination yields the rhombic triacontahedron, which is the reciprocal of the icosidodecahedron.

The cube, hexagonal prism, truncated octahedron, and rhombic dodecahedron all have an interesting space-filling property: each can be repeated by translations to form a kind of honeycomb to fill any desired amount of space without overlapping and without interstices. Another solid with the same property is Fedorov's elongated dodecahedron, which is obtained by holding a rhombic dodecahedron so that a vertex where four faces meet is at the top and stretching it so that the four vertical faces become four hexagons, meeting in pairs along four new vertical edges.

FIG. 3.—A SELF-RECIPROCAL POLYHEDRON

Fig. 3 shows a polyhedron with four triangles and four trapezoids as faces. It may be regarded as a modified regular octahedron that has had two opposite vertices replaced by two new edges, both parallel to (but shorter than) two of the original edges; thus $V = F = 8$ and $E = 14$. This polyhedron shares with the pyramids the property of being self-reciprocal (*i.e.*, similar to its reciprocal, though differently placed). It is the simplest centrally symmetrical polyhedron of this kind; there are infinitely many others.

SOLID STATE PHYSICS deals with the physical properties, behaviour, and internal structure of solid materials. Although fundamental in relating the characteristics of solids to basic physical laws, the subject has spawned important technological developments. The topic is so broad that many aspects of solid state physics are treated separately, as in PIEZOELECTRICITY; THERMIONICS; ELECTRICITY, CONDUCTION OF.

A solid has been defined as any body that tends to return to its original shape after forces applied to it have been removed. This definition fails to draw a distinction between solids that undergo slow deformation (creep) when they are loaded, and thixotropic liquids that behave in a gelatinous fashion under small stresses and do not flow under small loads. The reason is that a sharp boundary between what are thought of as ideal solids and ideal liquids does not seem to exist in nature.

This article is organized as follows:

I. HISTORICAL DEVELOPMENT

In the 16th century a new interest in natural crystals was part of the Renaissance growth of science in Europe. Systematic measurement with the relatively crude tools of the day showed that crystals often are anisotropic; *e.g.*, their mechanical or optical properties differ from one crystal axis to another. By 1830 crystalline materials had been divided into 32 classes on the basis of symmetry; some are completely anisotropic (*i.e.*, have no two directions with the same properties); another class has 48 symmetry elements corresponding to a cube. Angles between crystal faces were found to be accurately the same for each mineral regardless of the source or the chance form of a given specimen (*see* CRYSTALLOGRAPHY). This macroscopic type of study reached its peak late in the 19th century; although it still attracts great interest as a source of data concerning the uses to be made of crystals, it is no longer the central field of research.

Lattice Theory.—Late in the 18th century interest arose in the origin of the remarkable regularity and symmetry of crystals. With the development of atomic theory it seemed clear that the macroscopic properties reflect a highly ordered arrangement of atoms or molecules. A. Bravais, at mid-19th century, proposed that the molecules in crystals are arranged in regular three-dimensional lattices; that is, he supposed all crystals to have translational symmetry in three directions. He showed that this hypothesis would account for the 32 symmetry types found in nature. By 1890 W. Barlow, E. S. Federov, and A. Schoenflies had demonstrated that 230 types of lattice symmetry (*i.e.*, 230 space groups) are possible. Little was known about the arrangements of atoms in lattices although ingenious proposals were made for the simpler crystals such as rock salt.

Lattice theory came into its own in 1912 when M. T. F. von Laue (*q.v.*) and colleagues demonstrated that lattice spacing in typical crystals permits them to diffract X rays much the same as a finely ruled grating will diffract ordinary light. This discovery permitted the measurement of X-ray wavelengths (*see* SPECTROSCOPY, X-RAY) and the structural study of many crystals. Within ten years the structures of many simple inorganic materials were known; during the 1920s analysis was extended to more complex inorganic minerals, and after 1930 to organic crystals. X-ray techniques also revealed imperfections in lattice structure through deviations from ideal diffraction. X-rays were later supplemented by electron and neutron (*qq.v.*) diffraction.

Electronic Properties of Ideal Crystals.—Soon after discovery of the electron (late 19th century) great interest arose in the role electrons play in matter. P. K. L. Drude and H. A. Lorentz (early 20th century) presented an incomplete theory that the valence (*q.v.*) electrons in many metals behave as a gas that is free to move under electric and magnetic fields. Similarly, E. Madelung and M. Born developed a particularly useful theory that ionic crystals are composed of regular arrays of the ions found in aqueous solutions.

By 1930, through the use of quantum statistics, A. Sommerfeld had essentially modified the Drude-Lorentz theory of metals, successfully applying it to problems in electrical conductivity. Studies of the behaviour of electrons in a potential field possessing lattice symmetry led to the development of the band theory of solids (discussed below) and provided clarification of the striking differences among the ideal crystal types. Semiconductivity was explained semiquantitatively by A. H. Wilson and N. F. Mott, while L. D. Landau and R. Peierls turned to the interaction of electrons in solids with magnetic fields. In 1932 E. P Wigner and F. Seitz discovered a practical method for calculating wave functions for simple solids; it was later extended by J. C. Slater, C. Herring, and others. By 1940 a fairly detailed semiquantitative picture of the behaviour of electrons in solids was available.

After World War II more sophisticated calculations with high-speed computers and new experimental data on single crystals in electromagnetic fields yielded detailed information about electron energy levels in solid materials. By the 1960s the electronic structure of simpler metals and of a few valence semiconductors was known quantitatively, and that of many other inorganic solids was known semiquantitatively.

Imperfection-Determined Properties.—Clarification of those electronic properties that are determined by imperfections in ideal crystal structure developed slowly until the 1940s. Just prior to World War I, K. Baedeker noted that what are now known as impurity semiconductors owe their electrical properties to imperfections (*i.e.*, foreign atoms). In 1927 J. Frenkel demonstrated that the electrolytic conductivity of ionic crystals is associated with mobile charged lattice imperfections; proposed models for such imperfections were amplified in 1930 by W. Schottky and C. Wagner.

By 1934 E. Orowan and G. I. Taylor had proposed models of those imperfections (called dislocations) that accounted for the plastic properties of ductile crystals. Thus the importance of imperfections in crystals was appreciated by 1940; however, reduction to relatively broad principles came only after World War II.

Later Developments.—High-purity silicon and germanium (*qq.v.*) became available after World War II and, along with increasing understanding, led to high-quality semiconductors with reproducible and controllable properties. As an outgrowth, the point-contact transistor was invented by J. Bardeen and W. H. Brattain (1948), followed by the development of junction rectifiers, the junction transistor, and in 1954 by a solar photovoltaic cell of relatively high conversion efficiency. In 1957 L. Esaki found an anomalous current-voltage relationship in narrow P-N junctions that led to the tunnel diode.

Solid-state advances revolutionized the electronics industry, providing a host of low-impedance devices (*see* ELECTRICITY: *Induced Electromotive Forces*) and allowing substantial miniaturization of electronic components. In the 1960s interest centred on devices made from thin films (produced by evaporation, chemical deposition, or epitaxial crystal growth), spawning a field called microelectronics.

For many years magnetic iron oxide (magnetite: Fe_3O_4), a ferromagnetic insulator, was a scientific curiosity. During World War II J. L. Snoek developed magnetic oxides (ferrites) with the same crystal structure as magnetite; these have found many high-frequency applications because their eddy-current losses are small. The use of ferrites in radio-frequency inductors and transformers also contributed to the miniaturization of these electronic components.

H. Kamerlingh Onnes' discovery of superconductivity (*q.v.*) in 1911 promised the production of powerful, sustained magnetic fields by currents flowing in wires at temperatures approaching absolute zero. Unfortunately, intense magnetic fields tend to destroy superconductivity. In 1961 certain alloys were found to carry substantial current densities in fields approaching 100,000 gauss without losing superconductivity. Solenoids constructed of these materials offer convenient sources of intense magnetic field, and despite the need to maintain them at low temperature, they are much more economical to operate than are sources using conventional materials. Most applications of powerful magnetic fields were expected to benefit; *e.g.*, in the development of new communication devices (*see* LOW-TEMPERATURE PHYSICS).

II. PHYSICAL PROPERTIES OF SOLIDS

1. Types of Solid.—Crystalline solids have a very high degree of order in atomic arrangement; practically all metals and minerals are of this type. Noncrystalline solids (including glass, plastics, and gels) are those in which the atoms and molecules are not arranged in a definite lattice pattern.

Four distinct types of crystalline solid may be recognized: metals and alloys; salts (ionic crystals); valence crystals; molecular crystals. Metals and alloys are distinguished by their high electrical and thermal conductivity and metallic lustre. The conductivity of metals and alloys is known to arise from migration of free electrons. Salts are commonly formed from ionic solutions and may be viewed as aggregates of charged ions. They commonly have ionic conductivity that increases with temperature. Valence crystals are hard, often brittle, materials such as diamond, silicon, germanium, and silicon carbide. The more abrasive types have high melting points. Like salts, they tend to form in accordance with the rules of valence (*q.v.*) chemistry. In simpler monatomic

types (such as diamond) each atom is surrounded by a number of atoms equal to its valence. Unlike salts, they are not ionic conductors in the pure state and cannot be formed by aqueous precipitation. Molecular crystals are solids such as dry ice (carbon dioxide), the solid forms of the rare gases, and crystals of many organic compounds; these have relatively high vapour pressure at ordinary temperatures (*see* VAPORIZATION). Their sublimation products, such as CO_2 gas in the case of dry ice, are usually stable molecules.

Many alloys, salts, valence crystals, and molecular crystals that are good electrical insulators at low temperatures become conductors at elevated temperatures, conductivity increasing rapidly with temperature. Such materials are termed semiconductors. Their electronic conductivity is usually low compared with that of such metals as copper, silver, or gold, in which conductivity decreases with increasing temperature. In general, the class cuts across the four types of crystalline solid. Some (*e.g.*, silicon, germanium, and tellurium) are semiconducting even when highly purified; others are semiconductors only when appropriate foreign additions are present, or when their composition deviates from ideal combining proportions. The two types are commonly called intrinsic and impurity semiconductors. Cuprous oxide and zinc oxide are typical impurity semiconductors. Actually, the conductivity of most intrinsic semiconductors can be altered substantially by suitable additions of impurities. Semiconducting solids attracted early interest (*c.* 1920) because of their ability to act as electrical rectifiers.

Most crystalline solids have the properties of two ideal types. For example, silicates have properties that resemble those of both salts and valence crystals; many alloys (such as Mg_3Sb_2) have compositions that resemble those of ionic crystals. Most noncrystalline organic materials have properties common to molecular and valence crystals. They frequently are composed of large molecules, between which there is a relatively weak cross-linkage and an occasional strong valence bond. Most types of glass lie between the ideal valence and ionic types. It is noteworthy that ideal metals (and alloys) and ionic substances always form crystalline solids.

2. Atomic Structure of Solids.—Differences among solids may be ascribed to differences in the forces between their atoms and to differences in the way the atoms are arranged. It is a general principle that atoms attract one another when far apart and repel one another at small separations (*see* fig. 1). If the energy of interaction is arbitrarily chosen to be zero at infinite separation, it is found first to decrease as the atoms approach one another, and then to increase very rapidly as they come very close together. The separation at which the minimum occurs is that for which the forces of attraction and repulsion are at equilibrium and represents the separation of atoms in the diatomic molecule. The depth of the minimum and the position at which it occurs depend on the chemical species of the atoms. Thus, the minimum is shallow for two atoms of the rare-gas type and very deep for atoms that form strong chemical bonds. The depth of the minimum is a direct measure of the strength of the bond between atoms.

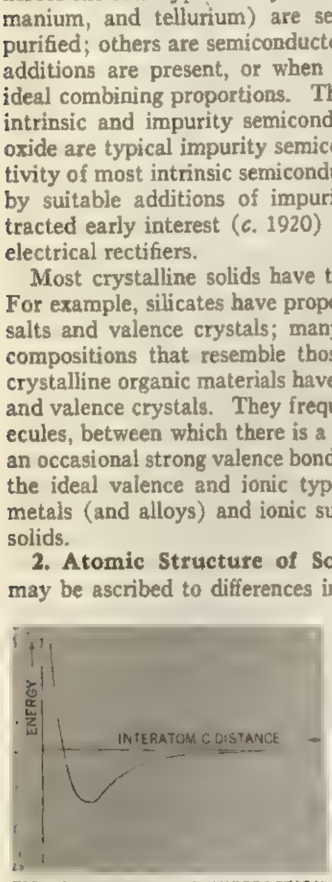

FIG. 1.—ENERGY OF INTERACTION OF TWO ATOMS AS A FUNCTION OF INTERATOMIC SPACING

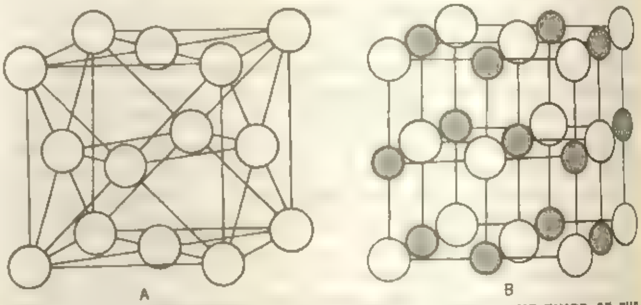
The energy of interaction between any pair of atoms usually changes in the presence of other atoms. As a result, it is not feasible in general to determine the cohesive forces in a solid by treating it as composed of isolated pairs of atoms. But it is still useful for qualitative work to regard each atom as a definite sphere of fixed diameter that attracts neighbouring atoms, the sign of the forces reversing on contact. Many empirically observed properties of solids can be accounted for in terms of this simple rigid sphere concept (*see* ATOM: *Size and Mass of Atoms*). Assuming spherical structure, the distance between the centres of adjacent atoms in a sample of pure elemental substance is equal to the atomic diameter; similar considerations hold for ionized (charged) atoms. The following table gives estimates of typical atom and ion diameters as determined from X-ray data.

Atom and Ion Diameters in Å (10^{-8} cm.)

H	0.74	F	1.36	F^-	2.66
C	1.54	Cl	1.94	Cl^-	3.62
Fe	2.48	Br	2.26	Br^-	3.92
Zn	2.66	Ga	2.66	Ga^{3+}	1.34
Ti	2.90	Na	3.72	Na^+	1.96
Li	3.00	K	4.54	K^+	2.66
Mg	3.19	Rb	4.86	Rb^+	2.98

The distribution of atoms in solids as determined with X rays is basically as follows:

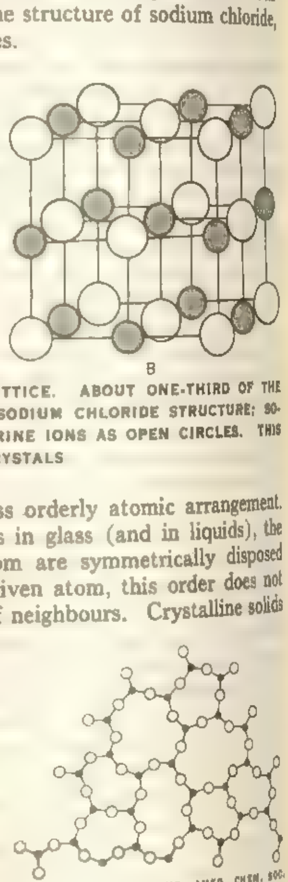
Within each individual crystal or grain in crystalline solids, the atoms are arranged in a three-dimensional lattice. Fig. 2A shows the face-centred cubic lattice characteristic of many metals such as copper and nickel; fig. 2B shows the structure of sodium chloride, characteristic of most alkali halides.



A B

FIG. 2.—(A) FACE-CENTRED CUBIC LATTICE. ABOUT ONE-THIRD OF THE METALS HAVE THIS STRUCTURE. (B) SODIUM CHLORIDE STRUCTURE; SODIUM IONS ARE SHOWN SHADED, CHLORINE IONS AS OPEN CIRCLES. THIS ARRANGEMENT IS TYPICAL OF IONIC CRYSTALS

Noncrystalline solids have a less orderly atomic arrangement. In the extreme case, which occurs in glass (and in liquids), the immediate neighbours of any atom are symmetrically disposed about it; however, relative to a given atom, this order does not extend beyond the first few sets of neighbours. Crystalline solids sometimes are characterized as having both long-range and short-range order; noncrystalline solids as having only short-range order. Fig. 3 shows the structure observed in boric oxide glass. Similarly, each silicon atom in silica glass is surrounded tetrahedrally by four oxygen atoms and each oxygen atom has two silicon atoms as nearest neighbours (*see* GLASS MANUFACTURE). Fibrous materials may have parallel long-chain molecules linked to produce an appreciable amount of long-range order relative to the fibre-axis; thus rubber and similar plastic substances (*see* PLASTICS) frequently show semicrystalline structure under tension.



W. H. ZACHARIASEN, JOUR. AMER. CHEM. SOC.

FIG. 3.—TWO-DIMENSIONAL NETWORK OF BORIC OXIDE GLASS. THE STRUCTURE LACKS PERIODIC (LONG-RANGE) SYMMETRY

3. Chemical Composition.—Most solids with low electrical conductivity (*e.g.*, saturated hydrocarbons; oxides and chlorides of the simpler metals) conform to the usual rules of combining proportions summarized in elementary valence chemistry. Specific examples include alkali halides, magnesium oxide, and paraffins. This obedience to simple valence theory is reflected in the definite and simple way their atoms are arranged. In crystalline materials each type of atom forms its own lattice; the complete lattice may be regarded as a combination of these lattices. Similarly, in insulating noncrystalline solids, the short-range order shows regularity and simplicity, as in the case of silica glass.

Metals, in combining with each other, do not obey the usual rules of valence. They tend to combine over wide ranges of composition; *e.g.*, copper will dissolve up to 30% of zinc without

altering its face-centred cubic lattice structure. They commonly form compounds that bear little relation to the usual rules of combining proportions. Thus copper and zinc form compounds of approximate composition CuZn, Cu_5Zn_8 that differ in lattice structure (*see* INTERMETALLIC COMPOUNDS).

W. Hume-Rothery and G. Hägg, respectively, attempted to systematize rules of combining proportions of metals for substitutional and interstitial alloys. In substitutional alloys, atoms of one type are replaced by another as composition is varied. For example, copper atoms are replaced by zinc as the amount of zinc in brass is increased. Interstitial alloys differ in that one type of atom is sufficiently small to fit into the interstices of the lattice formed by the other. Typical interstitial alloys are formed by dissolving carbon in iron or hydrogen in palladium (*see* ALLOYS).

Hume-Rothery noted that substitutional alloys form for wide ranges of composition as long as the atomic diameters of the constituent elements do not differ by more than 15%. When the difference in diameter is more than this, few substitutional phases form and these have very narrow solubility ranges. He found a close relationship between the crystal structure of a substitutional alloy and the ratio of the number of valence electrons within it to the number of atoms. For example, the body-centred cubic lattice, characteristic of beta brass (CuZn), forms whenever the ratio of valence electrons to atoms is 1.5. In beta brass, each zinc atom contributes two valence electrons and each copper atom contributes one, so that the ratio is 3:2 = 1.5. The corresponding phase in the bronze (tin-copper) system has the approximate composition Cu_5Sn.

Hägg found that interstitial alloys form readily if the metals are very close in the electromotive series (*see* BATTERY) and if the diameter of one atom is less than 0.59 times that of the other. The only systems of alloys that satisfy these conditions are those that combine the so-called metalloid atoms (hydrogen, boron, carbon, and nitrogen) with the transition metals, such as those of the iron, platinum, and palladium groups. The metalloid atoms fit the interstices of the metal-atom lattices. Hägg also found a close correlation between composition and structure among the interstitial alloys.

Two elements will not alloy well if the ratio of their diameters falls in the range 0.59–0.85. Within this range the smaller atom is too large to fit into the lattice interstices of the other, and too small to form an ideal substitutional alloy. The range is a kind of no-man's land for alloy formation. The ratio is close to 0.59 for the iron-carbon system; were it somewhat larger we might have been denied the valuable alloy system of steel.

The relatively feeble electronic conductivity of intrinsic semiconductors indicates that they lie between ideal metallic solids and ideal insulators. Practically all the impurity semiconductors also fall between insulators and metals. Either they have appreciable solubility for foreign atoms having appropriate size relations, or they are compounds that tend to form over an appreciable range of composition. Ferrous oxide (FeO), a typical semiconductor, tends to deviate from ideal combining proportions by about 1%. Similar deviations are observed in zinc oxide; lead sulfide, selenide, and telluride; cuprous oxide; and even in alkali halides transformed into semiconductors by heating with alkali metal vapour. In such cases the crystal lattice exhibits imperfections on an atomic scale that are distributed throughout the specimen. Thus in iron oxide some lattice sites that would be occupied by iron ions in the normal crystal are vacant. In zinc oxide the deviation from ideal composition is associated with the presence of interstitial zinc atoms in the lattice of the oxide. The electronic conductivity of any of these semiconductors increases with the degree of deviation from ideal composition.

4. **Principles Determining Physical Form.**—The laws of thermodynamics (*q.v.*) indicate that the stable state of a system at constant pressure is determined by the condition that the free energy

$$F = E + PV - TS \tag{1}$$

be a minimum. Here E is the energy of the system, P is external pressure, V is volume, T is temperature, and S is the entropy. Variations in PV that normally occur when solids are maintained at atmospheric pressure are negligible, so that this term may be discarded. It usually is adequate for practical purposes to use

$$F = E - TS \tag{2}$$

At absolute zero temperature the TS term vanishes and the equilibrium state is determined by the condition that E be a minimum. This is just the condition for equilibrium in a mechanical system. Thus the TS term in equation (2) acts as a correction for the influence of temperature fluctuations in altering the equilibrium value from what it would be at absolute zero. As the temperature of a solid rises, energy is absorbed and E increases. The entropy S, which measures the thermally induced disorder of the system, also increases. Thus the terms on the right side of equation (2) compete as temperature rises, E tending to increase and TS to decrease F. At low temperatures atoms in solid systems tend to be in highly ordered arrangements for which E is small; at high temperatures disordered states for which S is large are favoured. The tendency toward disorder as temperature rises may be manifested in one or more of several ways.

The atoms are set into oscillation about positions of equilibrium that theoretically obtain at absolute zero. This type of disordering is universal for solids at any given temperature above absolute zero.

The system may change from one lattice structure to another in which the atoms have greater freedom of movement. This is termed an allotropic transformation and is very common. For example, iron changes from the body-centred cubic to the face-centred cubic lattice at 910° C (*see* IRON AND STEEL INDUSTRY: *Steel Metallurgy*). Sulfur exhibits several allotropic transformations at successively higher temperatures. (*See* also PHASE EQUILIBRIA; SULFUR.)

Pairs of atoms of different types may change places to disorder the lattice. This interchange is most commonly observed in alloys, in which the net energy required for interchange is smaller than for materials in which the constituents differ widely (*e.g.*, salts). For example, at absolute zero temperature the stable form of beta brass (CuZn) is a body-centred cubic structure in which one type of atom occupies the body-centred positions and the other occupies the position at cube corners. As temperature rises, atoms begin to change places until, at 480° C, it is equally probable that a given position will be occupied by either type of atom. The basic lattice remains unchanged in this type of transformation.

A similar kind of disorder may arise through rotation (libration) of individual molecules or radicals in molecular crystals of salts such as ammonium chloride.

Disordering may result from occasional migration of atoms to interstitial positions in the lattice or to the surface, leaving the lattice with vacant sites. The number of disordered atoms, or lattice defects, per unit volume increases rapidly with temperature, obeying the same law as does the density of vapour above a liquid. Diffusion (*q.v.*) and ionic conductivity in solids are intimately related to lattice defects of this type. Diffusion occurs in substitutional alloys because vacancies produced in the lattice by migration of atoms to the surface can move from one site to another. Their motion permits a shuffling of atoms within the lattice. Similarly, ionic conductivity of alkali halides is related to migration of vacancies for halogen and alkali-metal ions.

It is evident that changes from solid to liquid or gaseous state represent even more extreme types of disordering; nevertheless, melting and sublimation obey the same basic principles.

Motion of free electrons is responsible for the high thermal and electrical conductivity of metals. The free electrons may contribute to disorder by an increase in their rate of motion. Ferromagnetism (*q.v.*) originates in an ordered coupling of a fraction of the valence electrons. This order is disrupted at elevated temperatures and the ferromagnetism vanishes, *e.g.*, it disappears at 780° C in iron.

The onset of disorder increases the internal energy of the system and requires the absorption of a corresponding amount of thermal energy. This absorbed energy is evident as the specific heat necessary to raise the temperature, or the latent heat of phase transi-

tion. It frequently is possible to identify the nature of the disordering process by its contribution to the absorbed thermal energy. For example, change in specific heat associated with an increase in amplitude of oscillation of the atoms varies as the third power of the temperature near absolute zero and reaches a limiting value at high temperatures (*see* CALORIMETRY).

Allotropic changes like melting are accompanied by the appearance of a latent heat at the temperature where the phase change occurs. The observation of this latent heat is commonly used to detect allotropic changes (*see* LATENT HEAT).

Onset of order-disorder in alloys and of molecular rotation in molecular solids is usually distinguished by a large increase in specific heat over the temperature range near that at which disordering (or rotation) becomes complete. The transition may also be marked by the appearance of a latent heat.

Disorder associated with electron changes is also marked by thermal effects. For example, free electrons in metals make a contribution to the specific heat that increases linearly with temperature; it is particularly large in the transition metals such as iron and nickel. Similarly, disappearance of ferromagnetism in iron is accompanied by a peak in specific heat of the type observed during the disordering of alloys.

5. Elasticity.—Recall that each atom in a solid is normally at equilibrium with its neighbours. The atoms take up new positions when external forces are applied, *i.e.*, when the solid becomes strained. As long as the applied forces are sufficiently small, the atoms return to their original positions when the forces are relieved, and the strain is said to be elastic. The material is strained beyond its elastic limit when the process is not reversible. The range of elasticity depends much on the nature of the applied forces, and on the material and history. Most homogeneous materials are highly elastic under hydrostatic pressure. In general, a tensile stress, or a unidirectional compressive stress, or a shearing stress is necessary for a deviation from elasticity.

P. W. Bridgman (*q.v.*) employed hydrostatic pressures as high as 100,000 atmospheres to produce large elastic strains. Changes in crystal structure may be produced by hydrostatic pressure and occasionally persist after the pressure is removed. Pressure approaching 100,000 atmospheres and temperature in excess of 2300° K were used by others to convert graphite into diamond. Bridgman discovered a variety of forms of ice at high pressures, most of which sink in water (*see* ICE).

For small pressures the relation between stress and strain is linear for small stresses; however, quadratic and higher terms appear in the stress-strain relation at elevated pressures. If no phase change is induced by the pressure, ever-increasing pressure is required for the same increment of strain. This decrease in compressibility as the pressure increases results from an increase in repulsive forces between atoms with decreasing atomic separation (fig. 1). The linear force-strain relation for small forces arises because interatomic forces vary linearly for small displacements.

Although hydrostatic pressure can produce a large elastic deformation, the range of elastic strain is much more limited for shearing stresses or tensile stresses. In such cases the material either flows plastically or breaks before the absolute magnitude of the stress components becomes as large as those in Bridgman's experiments. Work is done on a solid strained under applied forces. The reversible component of this work represents a change in the free energy of the solid; the elastic properties may readily be described in terms of changes in free energy that accompany atomic displacements associated with strains. In most solids this change in free energy is principally a function of change in E, the internal energy of the material; that is, the TS terms in equation (2) merely determine the relatively small amount by which the elastic constants at a finite temperature differ from those at absolute zero. There are, however, notable exceptions; for example, the elastic properties of rubber are principally related to how entropy changes as the material is strained. The elastic constants of materials of this type are usually strongly dependent on temperature.

6. Plasticity.—Most noncrystalline solids (*e.g.*, glass) become brittle at low temperatures; their elastic range is determined by the stresses at which they break. Many crystalline solids, however (notably metals), exhibit surprising ductility even near absolute zero. This type of plastic flow in large single crystals was found to obey several laws.

Crystals deform plastically by displacement of one part of the crystal relative to another along particular crystallographic planes (*see* CRYSTALS, DISLOCATION OF). These slip planes (or glide planes) are the octahedral planes of closest packing in face-centred cubic crystals and are the basal planes (those normal to the hexagonal axis) in hexagonal crystals. There are three different types of slip plane in body-centred cubic metals. Displacement along a given plane may even be visible to the naked eye or under a low-powered microscope. The crystal shows lamellae that are displaced like cards when a deck is sheared. X-ray evidence indicates plastic flow even within the lamellae.

In general, slip will occur in a given set of parallel planes only if the resolved shearing stress exceeds a critical value that depends on the previous history of the specimen and on its purity. This critical shearing stress σ_c increases as the amount of plastic strain increases, a phenomenon referred to as work-hardening; thus solids become harder as they are deformed by drawing or rolling. Critical shearing stress may also be raised by soluble impurities; in this way metals such as copper, silver, and gold can be made sufficiently hard for coinage. Values of σ_c for pure metals annealed at elevated temperatures range between 1 and 100 kg./cm.^{2}; values as high as 1,000 kg./cm.^{2} are common for work-hardened or alloyed metals.

There is a more or less well-defined temperature above which the effects of work-hardening may be removed by annealing in a reasonable time, perhaps half an hour. This resoftening temperature for metals such as lead, zinc, and tin is near or below room temperature; however, it is well above room temperature for many useful metals. Resoftening probably occurs at all temperatures above absolute zero, but is negligibly slow below the resoftening temperature.

Critical shearing stress is slightly dependent on temperature below the resoftening point; *e.g.*, the value for very pure zinc was found to increase from 75 to 140 kg./cm.^{2} in going from room temperature to 20° K (−253° C). This means that metals retain much of their ductility at low temperatures; *e.g.*, zinc bends under its own weight near absolute zero.

The high ductility of metals appears related to the presence of imperfections. If two parts of an ideally perfect crystal were to be displaced relative to one another along a slip plane as rigid units, the stresses required would be about $\frac{1}{10}$ of Young's modulus (*see* ELASTICITY; MATERIALS, STRENGTH OF); that is, about 500,000 kg./cm.^{2}. This is at least 1,000 times larger than the values normally observed in pure single crystals. Hairlike microscopic crystals about 0.0001 in. in diameter sometimes have this theoretical strength. Such crystals probably lack the imperfections responsible for the ductility of most materials.

7. Fracture.—From the above discussion the rupture stress of an ideal crystal (*i.e.*, the stress required to break chemical bonds) is seen to be about $\frac{1}{10}$ Young's modulus for the material. The fact that materials usually break under much lower stresses probably arises from magnification of stress in the vicinity of small (even submicroscopic) cracks. If the magnified stress is large enough the cracks will propagate, weakening the material, shifting the applied load to a smaller effective cross-sectional area of crystal, and activating a new set of microcracks. Such a chain of events leads to fracture, the applied stress required being called the fracture stress.

Recall also that critical shearing stress for plastic flow (*i.e.*, the stress needed to move dislocations through the crystal) is also much lower than ideal rupture stress. Whether the material fractures abruptly or yields plastically depends on which of the two (fracture stress or critical shearing stress) is lower. If fracture stress is lower the material is brittle; lower critical shearing stress produces ductile behaviour. Presumably glass is brittle at low temperatures because its nonperiodic structure does not allow easy movement of dislocations. Ionic crystals usually show brittle fracture, but the fracture stress seems strongly dependent on surface condition. Small surface flaws apparently have associated micro-

cracks that produce substantial stress magnification. Alkali halide crystals can be bent in a ductile manner when immersed in water, and ductile behaviour has been reported for crystal specimens plated with a thin layer of a soft metal.

At normal temperatures pure metals deform in a ductile manner because critical shearing stress is relatively low, while fracture stress is much higher. Onset of plastic flow relieves stress concentrations, preventing local stresses from greatly exceeding average stress level. Extreme work-hardening will raise critical shearing stress above fracture stress, and the metal can be made to break in a brittle manner.

Yield stress in metals increases more rapidly than does fracture stress as temperature drops; thus a normally ductile metal can become brittle at lower temperatures, as in the brittle failure of steel.

8. Electrical Conductivity.—The electrical resistivity of solids covers a wide range. At normal temperatures the resistivity of a typical metal is 10^{-6} ohm-cm., while that of fused quartz (a good insulator) is about 10^{20} ohm-cm. (*see* INSULATING MATERIAL [ELECTRICAL].) Alloys, semiconductors, and less efficient insulators fall between these extremes. As temperatures approach absolute zero the resistivity of a pure metal falls markedly; depending on residual impurity content, this decrease may be as much as 100,000 times.

Solids can conduct electricity if they contain mobile ions. The probability that a given ion will become sufficiently free (as a result of thermal fluctuations) to jump from one equilibrium position to another determines conductivity in this case. Ionic conductivity is not very large, however, and solids that conduct only in this way are usually among the less efficient insulators; they also conduct much better at high temperatures.

If a solid contains free electrons, its total conductivity will heavily overshadow any ionic conductivity present; thus good electrical conductors are characterized by electronic conductivity. One of the greatest achievements in applying quantum mechanics to solids was in understanding electronic conduction in metals and semiconductors. It is known that energy levels for electrons in solids fall into quasi-continuous bands separated from each other by forbidden regions called energy gaps. A metal is characterized by a partially filled band of electrons or by a group of partially filled overlapping bands. In such a situation electrons are present adjacent to unoccupied levels, and can be excited into the empty levels by absorbing energy from the electric field. The upshot is that a substantial fraction of the electrons in a metal behave as if they were free.

If the number of electrons in a solid is just sufficient to fill one of the quasi-continuous bands of energy levels, and if this band is separated from other bands by substantial energy gaps, the material is an insulator. However, a number of circumstances perturb this ideal situation: If an energy gap is not too large, some thermally excited electrons may cross it, leaving vacant levels in the nominally filled band, and putting some electrons into a practically empty band; this represents an intrinsic semiconductor. Through inclusion of suitable impurities the electron-atom ratio in the solid can be increased to force some electrons into a vacant band, or decreased to partially empty the original band; this describes an extrinsic semiconductor. The number of electrons that participate in conduction in a semiconductor is quite small on a per-atom basis. In an extrinsic semiconductor the number varies from 10^{-5} to 10^{-8} electrons per atom; in intrinsic semiconductors it is even smaller.

Through quantum mechanics it is indicated that metals can have infinite conductivity if all atoms are completely at rest and the lattice is perfect. Conductivity is limited only because free electrons accelerated by the applied field are deflected by lattice imperfections. Most important of these imperfections in a pure metal at ordinary temperatures are those arising from thermal vibrations of the lattice. Foreign atoms also make an important contribution to the resistivity of impure metals and alloys, and are the principal source of residual resistance in pure metal crystals at very low temperatures.

The conductivity of most electronic conductors is modified in a magnetic field. The effect is particularly pronounced in pure materials at temperatures near absolute zero. In most cases conductivity is reduced because conduction electrons are continually deflected by the magnetic field, increasing the length of their overall trajectories. The electrical conductivity of isotropic solids or cubic crystals may be regarded as a scalar quantity until a magnetic field is applied. The current then no longer need be in the direction of the applied electric field; in other words, the scalar conductivity is replaced by a tensor conductivity (*see* ANALYSIS: *Tensorial Functions*). Electrical properties of metals and semiconductors have been studied in magnetic field strengths up to 200,000 gauss. Such experiments have yielded considerable information about electron energy levels in single crystals.

Electrical conduction in a temperature gradient is subject to thermoelectric effects, and a circuit of two dissimilar materials can produce electrical energy from heat. The origin of such effects is understood in terms of electronic band structure, and measured thermoelectric coefficients give information about electron energy levels in the solid under study.

Some metals and alloys become superconducting at very low temperatures, abruptly losing all resistivity near absolute zero. Superconductivity (*q.v.*) was first observed in metallic mercury, and many other superconductors have been found, each with a distinct superconducting transition temperature. The highest transition temperature known in the 1960s was that of niobium tin (Nb_3Sn) at 18.05° K. J. E. Kunzler and co-workers (1961) discovered that some hard superconductors (*e.g.*, Nb_3Sn or niobium-zirconium alloys) could carry large current densities in magnetic fields approaching 100,000 gauss. This discovery opened the door to high-intensity magnets that can operate without electrical power dissipation; in 1965 a magnet cooled with liquid helium was reported to develop 132,000 gauss using only six automobile batteries as a power source.

Onset of superconductivity is accompanied by a marked change in magnetic properties: the superconductor tends to expel the magnetic field, becoming an ideal diamagnetic (*see* DIAMAGNETISM). Most macroscopic aspects were correlated by F. London's and H. London's phenomenological theory (1935). Observing that superconducting metals are those with relatively high resistivity at normal temperatures, H. Fröhlich (1950) proposed that superconductivity arises when conduction electrons strongly interact with lattice vibrational waves. This approach was developed by Bardeen and others into a successful microscopic theory (1957).

9. Thermal Conductivity.—The high thermal conductivity of metals (as does their electrical conductivity) depends on a high density of essentially free electrons that transport thermal energy from hotter to cooler regions. When thermal conduction via free electrons is the dominant process, thermal and electrical conductivity tend to be proportional, independently of the detailed electronic level structure of the solid. This proportionality, the coefficient of which can be calculated theoretically, has been known (for more than 100 years) to hold for many metals at normal temperatures; it is known as the Wiedemann-Franz law.

Another important mechanism of thermal transport through solids is by lattice vibrations (frequently called conduction by phonons). Atoms in a crystal, interacting with forces that obey Hooke's law in first approximation, can be made to vibrate; *e.g.*, a sound wave with fixed frequency and direction of motion may be passed through the crystal, or vibrations can be stimulated by heating. When the crystal is heated at one end vibrational energy will increase there, and lattice vibrational waves will propagate to the cooler end. These waves carry more energy from the hot region than is transported back by waves from cooler parts. Such vibrational waves have corpuscular properties; their energies are limited to discrete values, much as light is quantized (*see* LIGHT: *History*). The excitation of a vibrational wave proceeds in steps, each excitation unit being called a phonon. Sometimes it is convenient to regard the phonons as a gas of particles that conduct heat as do molecules in gas, with the essential difference that phonons can be "created and destroyed" through energy transfer. Excess phonons arise in hotter regions of a crystal, propagate to cooler regions, and disappear.

Insulating crystals conduct heat by phonon transport. In semiconducting solids conduction by phonons is of comparable magnitude to electronic thermal conductivity.

10. Magnetic Properties.—All solids are influenced by a magnetic field, but in many cases very slightly. The five types of magnetic behaviour exhibited by solids are diamagnetism, paramagnetism, ferromagnetism, antiferromagnetism, and ferrimagnetism. The first two arise from orbital and spin motion of individual electrons, usually with a small effect on the magnetic field except at very low temperatures. The last three arise through cooperative interaction of a large fraction of the electrons in a solid, the magnetic moments of the atoms becoming aligned or ordered (*see* MAGNETISM).

Ferromagnetism is exhibited by the transition metals and by some of their alloys. Ideally ferromagnetism is depicted by complete alignment of the magnetic moments on the individual atoms (even in the absence of an applied magnetic field); as the solid is heated it reaches its Curie temperature, at which point the arrangement becomes so disordered that ferromagnetism disappears. Antiferromagnetism is represented by an ordering in which equal magnetic moments alternate, pointing in opposite directions to yield a net moment of zero. Ferrimagnetism is the most general type of magnetic ordering in solids; it is seen in ferrites, which are composed of more than one type of atom. While the alignment of one atomic species may be opposite to that of another, their unequal moments lead to a resultant magnetic moment other than zero. Magnetite (Fe_3O_4) is a mineral ferrite known since ancient times, but only since World War II has its magnetic structure (and those of related magnetic oxides) been understood. Although not as strongly magnetic as the metals iron, nickel, and cobalt, ferrites have the advantage of being electrical insulators, and serve in high-frequency applications where eddy-current losses in conducting materials otherwise would be very large.

Quantum theory has been used to account for differences among diamagnetic, paramagnetic, and ferromagnetic solids. Most prominent among these developments are a theory of paramagnetism in simple metals (W. Pauli); a theory of ferromagnetism (W. K. Heisenberg, F. Bloch, and others); a treatment of paramagnetic salts (J. H. Van Vleck); and an investigation of strongly diamagnetic metals such as antimony and bismuth (N. F. Mott and H. Jones).

At very low temperatures the magnetic susceptibility of single crystals of pure metals shows the oscillatory De Haas-Van Alphen effect when plotted against reciprocal magnetic field. The oscillatory behaviour results from a quantum effect that bunches the electron energy levels in the presence of a magnetic field. Measurements of the effect yield detailed information about electron energy levels in the solid.

After World War II, changes in absorption of high-frequency radio waves by solids in stationary magnetic fields received considerable attention. The energies of atomic nuclei and electrons depend upon their orientation in the magnetic field if they have resultant magnetic moments (*i.e.*, if they behave as tiny magnets). Nuclei of odd mass number and unpaired valence electrons usually have such magnetic moments. Electromagnetic waves of appropriate frequency can lose energy to the solid in changing the orientation of nuclei or electrons (*see* NUCLEAR MAGNETIC RESONANCE; ELECTRON PARAMAGNETIC RESONANCE). Studies of magnetic resonance have furnished much information concerning properties of solids and other systems.

In the presence of a magnetic field the conduction electrons of a metal or semiconductor move in orbits that are large compared to atomic dimensions. If the material is in a stationary magnetic field irradiated with high-frequency radio waves, the electrons can absorb energy when wave frequency coincides with their orbital frequency; this is called cyclotron resonance. Resonance studies of this type give information about the effective mass of electrons in solids.

11. Optical Properties.—The optical properties of a solid describe its behaviour under radiation from the infrared, visible, or ultraviolet parts of the electromagnetic spectrum. With overlapping band structure containing many vacant energy levels, metals strongly absorb infrared and visible radiation. On the other hand, because of the energy gap, a semiconductor does not absorb long-wavelength photons appreciably, showing strong absorption only when the energy of the photon is enough to lift an electron across the energy gap.

The colours of some metals and alloys, the transparency of alkali metals to ultraviolet, and the detailed shape of the absorption spectrum in semiconductors have been explained in terms of quantum mechanics (electron energy levels). In some high-resistivity semiconductors absorption of photons with enough energy to lift electrons across the gap can reduce resistivity significantly; such materials (*e.g.*, *see* SELENIUM) are called photoconductors. The photovoltaic effect depends on absorption of photons in a junction region between two extrinsic semiconductors (one conducts electricity by excess electrons and the other conducts by a deficiency). Devices utilizing the photovoltaic effect can convert solar energy into electricity with more than 10% efficiency (*see* PHOTOELECTRICITY; ENERGY CONVERSION, DIRECT).

III. THEORETICAL APPROACHES

The most important developments in the theory of solids after 1930 arose from the application of quantum mechanics to the behaviour of valence electrons. The approach closely resembles its application to molecular systems in that the coordinates of atomic nuclei are treated as parameters when the wave functions for the electronic states are determined. The procedure is permissible because the electrons move so much faster than the heavier nuclei that they may be regarded as being in a stationary state for each position of the nuclei (even when the latter are in motion, as in thermal vibration). This method of separating electronic from nuclear motion was introduced by Born and J. R. Oppenheimer and is accurate for most practical problems.

The complete wave function for the electrons in a solid is too complicated to determine precisely, and simplifications are usually made in solving problems.

1. One-Electron Approximation.—The electrons in the inner shells of an atom (which are not appreciably affected by changes in chemical binding) are treated as though rigidly attached to the nucleus; their influence on the valence electrons is assumed to be that they merely contribute a static potential field centred on the nucleus.

In first approximation each valence electron is assumed to possess its own wave function. This approximation (known as the Hartree-Fock method, or one-electron approximation) assumes that interaction between valence electrons again derives from a static potential field, but in this case a field calculated self-consistently. Although the results it yields are rough, and at best semiquantitative, it permits the motion of each electron to be described independently; that is, each electron can be assigned its own constants of motion. There are two ways in which the one-electron method is commonly used: atomic approximation and free-electron approximation.

In atomic approximation it is assumed that each electron is attached to a given nucleus or group of nuclei, as if it were in an isolated atom or molecule. Thus, the solid has the aspect of an aggregate of atoms or molecules, and is conceived as an insulator since the electrons are bound to definite nuclei and cannot move about the solid. This approximation is particularly useful in describing the normal state of a rare-gas solid (such as solid argon), a molecular solid (such as solid methane or any molecular solid with a low boiling point), or an ionic crystal (such as one of the alkali halides), where the electrons are bound to ions rather than neutral atoms or molecules.

In free-electron approximation it is assumed that each valence electron is free to move in the lattice so that its wave function has finite amplitude through the specimen. In the simplest case this function has the same form as that for a free electron; however, the approximation is not restricted to this simple situation. At first sight a solid described with free-electron functions seems to be a metallic conductor, since the electrons are free to wander everywhere. Actually, the motion of the electrons is restricted in certain cases so that they cannot conduct a current. The ground

state of any insulator may be described with equal accuracy with either free-electron or atomic approximation; thus, free-electron approximation is of more general use in treating the normal states of solids.

It may be asked if atomic approximation should ever be used; however, excited states described by the two one-electron approaches differ notably. Any neutral atom or molecule is characterized by excited electronic states in which electrons are bound to nuclei. Similarly, a solid described by atomic approximation may exhibit states in which excited electrons are bound to definite atoms or molecules so that the solid is not conducting. On the other hand, an excited state of a solid described with free-electron approximation is always conducting, even though the ground state represents an insulator. Thus, atomic approximation can describe excited states that cannot be treated appropriately by the free-electron approach. Nonconducting excited states have been observed in alkali halide crystals; in these cases atomic approximation is the more appropriate.

To summarize, free-electron approximation can always be used for metals and the ground state of insulators; atomic approximation is frequently better for the excited states of insulators; it also has sufficient flexibility to describe conducting excited states of insulators (analogues of ionized states of atoms and molecules).

Neither one-electron approximation furnishes an exact solution of the quantum mechanical equations of motion. In spite of this defect, one-electron methods provide useful qualitative pictures of the behaviour of electrons in solids and illuminate many experimental findings. The difficult problem of modifying the approximations to give more nearly exact solutions has been solved in a few simple cases. Better solutions were obtained with alkali halides, for which atomic approximation is almost exact, and with alkali metals, for which the free-electron approximation is almost correct.

Atomic Approximation.—In applying atomic approximation to insulating solids most of the concepts gained from studying isolated atoms and molecules may be used; for example, the idea of electron shells. Also used is the notion that no two electrons can move in a given orbit unless they have opposite spin; this essentially is the Pauli exclusion principle (*see* NUCLEUS: *Further Properties of Nuclei;* PERIODIC LAW; SPECTROSCOPY). This principle can also be expressed by saying that no two electrons can have the same one-electron wave function unless they have opposite spin; in this form it can be applied to the case in which free-electron approximation is employed.

Recall that a solid described by atomic approximation is necessarily an insulator because the valence electrons are not free to roam about the specimen. In addition, it may remain an insulator when the electrons are excited to higher states of motion provided the orbits of the excited electrons are still bound to the atoms. The excited electrons will become free if given sufficient energy for the same reason that atoms and molecules become ionized when excited sufficiently: only a finite energy is required to remove any electron from an atomic system. If the specimen is excited by light certain ranges of frequency may be absorbed that do not make the crystal conducting. This is the case in which there are nonconducting excited states. On the other hand, as the energy of the light quanta increases a point will be reached at which the electrons are freed and the specimen becomes photoconducting. Most of the common insulating solids behave according to this model. That is, they do not become conducting when irradiated with the longest wavelengths which are absorbed by atoms of the bulk material.

The insulating solid may contain impurity atoms, a stoichiometric excess of one of the constituents, or imperfections. In such case, the electrons attached to the foreign atoms, or those in the vicinity of the imperfections, will not be bound in the same way as the electrons of the bulk solid. As a result they will have their own characteristic excited states and ionization potentials. If these excited levels lie closer to the ground state than those of the bulk solid, the longest wavelengths of light absorbed by the specimen will be characteristic of the foreign atoms or imperfections. Hence an impure crystal may become photoconducting as a result of its impurities. Most photoconducting solids used in practice are of this variety. If electrons can be freed from the atoms of an insulator by thermal fluctuations at ordinary temperatures the solid evidently is an intrinsic semiconductor. Similarly, if an otherwise ideal insulator contains foreign atoms that may be ionized thermally at normal temperatures the material is an impurity semiconductor.

Free-Electron Approximation.—Electrons moving in identical orbits on different atoms are considered to have the same energy in atomic approximation. On the other hand, it is generally assumed that the electronic states have different energies in free-electron approximation. This result is a consequence of the Pauli exclusion principle which states that no two electrons in the same system can have the same set of quantum numbers.

The energy levels of individual electrons may be grouped into nearly continuous bands. Separation of neighbouring levels in a band decreases with increasing size of specimen and is so small in all practical cases that it cannot be resolved by direct measurement.

The different bands of levels may be separated or may overlap, depending on the material (fig. 4). In general, the larger the fluctuations in internal electric field, the greater the likelihood that the bands will be separated. It is more likely that the bands will be separated in a monatomic solid containing quadrivalent atoms, such as carbon, than in one containing alkali metal atoms, since the electrostatic field strength will be larger and will fluctuate more strongly in the first case. Similarly, it is more likely that the bands will be separated in a salt containing strongly charged ions than in a monatomic solid in which each is neutral.

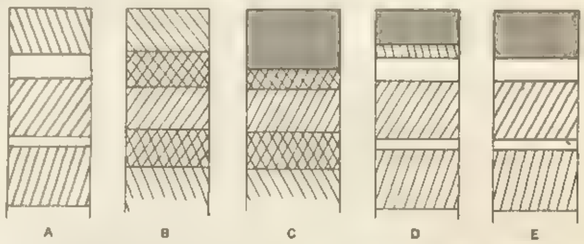


FIG. 4.—ENERGY LEVELS AS OCCUPIED BY ELECTRONS IN SOLIDS. HATCHED AREAS DESIGNATE QUASI-CONTINUOUS BANDS; SHADED AREAS, OCCUPIED LEVELS

(A) Quasi-continuous bands do not overlap; gaps represent forbidden regions of energy. (B) Bands overlap. (C) A metal; occupied levels border unoccupied levels infinitely closely. (D) A theoretical metal unknown in practice; uppermost occupied band only partly filled. (E) An insulator; occupied region extends to top of highest occupied band

Although the spacing between levels in a band is very small, the spacing itself is of practical importance because of the Pauli exclusion principle. A specimen of ordinary size contains about 10^{23} atoms and hence at least that number of valence electrons. Only two electrons at most can have the same wave function and these must have opposite spin. Although the energy levels are degenerate (that is, more than one wave function is associated with each), the degeneracy is small so that only a few electrons may occupy any given level. As a result the electrons are distributed over a large number of levels, or over a wide range of the spectrum. In the normal state of the solid the occupied levels will be those that lie as low as possible. Thus, all levels below a given point in the spectrum will be occupied as densely as possible. It is evident that the width of the occupied region depends upon the spacing of levels; hence, the importance of this spacing.

Under normal conditions the electrons in the densely occupied portion of the spectrum are so paired that there is no net flow of current even though each electron is moving through the solid very rapidly. In other words, for each electron moving in one direction there is another moving in the opposite direction at equal speed. If the bands overlap, it follows that the uppermost occupied level of the energy spectrum is always very near to the lowest unoccupied level (fig. 4C). Hence, when this type of solid is placed in even a very weak electrostatic field some electrons are excited into unoccupied levels, statistical balance of electron motion is upset, and current flows; this is characteristic of a metal.

Thus any solid in which the top of the occupied region is very close to unoccupied levels is a metal. This evidently will always obtain when the bands overlap, and even if the bands do not overlap provided the top of the occupied region does not extend to the upper edge of the highest band occupied (fig. 4D).

If the bands do not overlap and if the occupied range extends to the top of a band (fig. 4E), the solid will not be a metal. In this case the statistical balance among electrons can be disturbed only if the applied electrostatic field is so large (usually about 10^6 v./cm.) that electrons can be stimulated from the highest occupied band to the lowest unoccupied one. Thus, in free-electron approximation, an insulator is described as shown in fig. 4E in which the occupied region is separated from the unoccupied one by a large margin.

If the spacing between the highest filled band and the lowest empty band is sufficiently small, as in fig. 4E, electrons may be thermally excited to the upper band. A solid of this type will be a semiconductor even when pure and of ideal stoichiometric composition; that is, it will be an intrinsic semiconductor. The width of the gap may be determined from the dependence of electronic conductivity on temperature in such cases.

The crystal gains conductivity on electron transfer between bands because it now contains an unimpeded electron in a nearly empty band and the electrons in the filled band are no longer completely impeded, since one electron is absent. Such a nearly filled band is said to contain a hole, analogous to a bubble or void in an otherwise filled container of liquid. The hole acts as a positively charged particle, since a negative electron has left an otherwise neutral system. It has been shown that a hole behaves as a positive charge in electric and magnetic fields.

Considerable success has been achieved in determining the arrangements of bands and the manner in which they are occupied for a large number of simple solids. Reasonably accurate diagrams of the bands are available for many relatively simple metals and salts and for valence crystals such as diamond, silicon, and germanium.

Van Vleck and H. Brooks developed a method for relating the behaviour of the electrons in simple solids to the behaviour in the free atom without solving the equations of quantum mechanics directly. This method is successful in treating the cohesive properties of a number of simple solids, particularly metals. In a sense the procedure relates the properties of the solid to easily measured properties of free atoms without the complexities of solving the basic equations of the theory.

2. Cohesion.—The cohesion of a solid may be expressed in terms of the energy required to remove an atom from the surface to infinity; that is, the heat of sublimation, which can be computed once the energies of the electrons are known. The one-electron approximations usually fail to give accurate values of cohesive energy. More refined calculations made for simple solids (such as alkali metals and alkali halides) do, however, show reliable agreement with experimental data on bonding. The one-electron methods, on the other hand, have been adequate to estimate relative cohesive energies of different solids. Jones made a satisfactory interpretation of the Hume-Rothery rules with the use of band approximation, thus accounting for the importance of the electron-atom ratio in substitutional alloys. The same procedure was used to explain the comparatively great stability of metals with partly filled d and f shells.

IV. EXPERIMENTAL APPROACHES

Information about electron energy levels has been obtained by allowing solids to interact with electromagnetic fields. In metals such experiments provide information about the Fermi surface (the boundary between occupied and unoccupied levels). The experiments allow measurement of energy gaps in semiconductors, and yield information about electrons in the nearly empty bands or about holes.

A crystal is three-dimensional, and so is its energy-band structure; *i.e.*, detailed grouping of energy levels and the width of an energy gap depend on direction of motion of the electron in the crystal. Electron motion is wavelike, and may be described by a wave vector $\mathbf{k}$; thus electron energy is a function of the magnitude and direction of $\mathbf{k}$. In mathematical language energy $E = E(\mathbf{k})$. An electron energy level corresponding to the wave vector $\mathbf{k}$ with components $(\mathbf{k}_x, \mathbf{k}_y, \mathbf{k}_z)$ may be represented as a point in the three-dimensional wave-vector space. This space plays a fundamental role in the theory of energy bands; the Fermi surface is the boundary between occupied and unoccupied levels in the wave-vector space.

If the electrons were perfectly free (as they might be in an electron gas) the wave vector $\mathbf{k}$ would be simply proportional to the momentum $\mathbf{p}$ of the electron. In other words the De Broglie relationship $\mathbf{p} = \frac{h}{2\pi}\mathbf{k}$, or $|\mathbf{p}| = \frac{h}{\lambda}$ would hold, where h is Planck's constant and λ is the electron wavelength. The energy of an electron would thus be proportional to $\mathbf{k}^2$. For the lowest energy states in the gas to be populated, the Fermi surface would become spherical. In an actual solid the relationship between wave vector and momentum is more complicated; the Fermi surface is not spherical but its shape does reflect the basic symmetry of the crystal. Furthermore the energy gaps in the level structure depend on the direction of $\mathbf{k}$. The locus of energy gaps in $\mathbf{k}$ space is called the Brillouin zone boundary.

Fig. 5 shows the Fermi surface of copper as deduced from a theoretical model and experiment. The boundary of the first Brillouin zone is also shown. It is seen that the Fermi surface actually comes into contact with the Brillouin zone boundary at a number of points. If the potential field in the crystal were much weaker, the Fermi surface would approximate a sphere completely enclosed by the Brillouin zone.

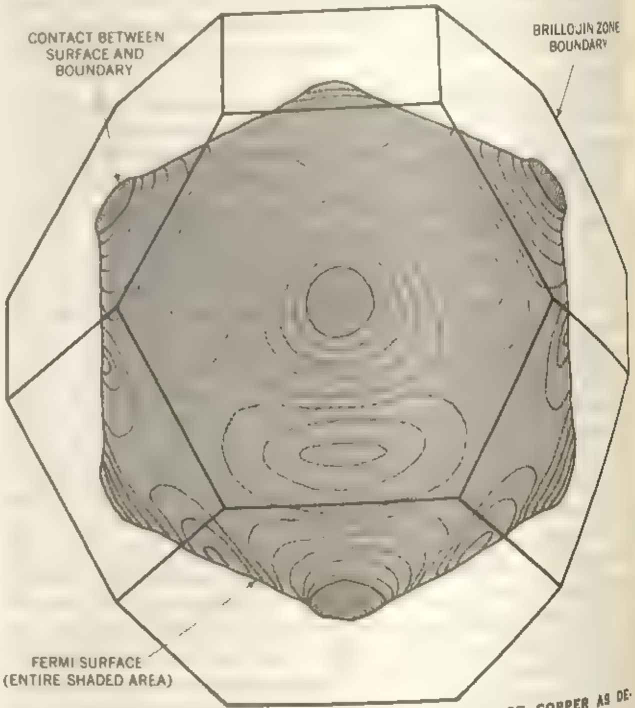

FIG. 5.—FERMI SURFACE AND FIRST BRILLOUIN ZONE OF COPPER AS DEDUCED FROM THEORY AND EXPERIMENT

1. Metals.—Various features of the Fermi surface for a given metal can be measured in separate types of experiment, and sometimes pieced together to get a good overall picture. These studies generally use a static magnetic field, and require single crystals of high purity; data are gathered at very low temperatures so that collision time for electrons is long compared with the time per orbit in the magnetic field.

De Haas-Van Alphen Effect.—The De Haas-Van Alphen effect involves oscillation in magnetic susceptibility observed in most pure metals at low temperatures when the magnetic field is increased or decreased. The oscillation has a constant period when the susceptibility is plotted against reciprocal magnetic field. Detailed calculations show that the period of oscillation measures

the extremal cross section of the Fermi surface in a plane perpendicular to the magnetic field direction. If the Fermi surface is complicated, several extremal cross sections may be present simultaneously, and the different periods corresponding to these cross sections beat together in the resulting oscillation. It is possible to separate the individual periods by means of Fourier analysis.

Cyclotron Resonance.—A static magnetic field moves the electrons in orbits about the magnetic field lines. If a high-frequency electromagnetic field is applied simultaneously, and if the frequency of this field coincides with the frequency of orbital motion, the electrons can absorb energy from the electromagnetic field. This is cyclotron resonance. The measured frequency of maximum absorption for a known static field is used to compute the effective mass of electrons at the Fermi surface.

Anomalous Skin Effect.—At high frequencies the electric current carried by a metal is confined to a thin surface layer of thickness called the skin depth. If the electron's mean free path for making a collision is large compared to the skin depth the conduction is called anomalous. The measured surface impedance of the metal in the anomalous range can be translated into a measurement of total free area of Fermi surface (*i.e.*, Fermi surface area not in contact with a Brillouin zone boundary).

Magnetoacoustic Absorption.—Magnetoacoustic absorption is anomalous attenuation of acoustic waves as they propagate through metal under a static magnetic field. When acoustic-wave frequency is appropriate to the frequency of electronic motion in the magnetic orbits, the electrons in the solid can absorb energy from the wave. In this type of experiment several values of magnetic field that lead to strong attenuation of waves of a fixed frequency are measured and can be used to determine dimensions of the Fermi surface.

Magnetoresistance.—Recall that the electrical conductivity of a material is modified by the presence of a magnetic field. If the limiting behaviour of the resistivity in strong magnetic fields can be determined, it can shed light on the topology of the Fermi surface. Specifically, if the orbit in wave-vector space of an electron at the Fermi surface touches the Brillouin zone boundary at a number of different points, the asymptotic behaviour of the resistance will differ from the case where the orbit does not touch the boundary. The quite complicated theory of magnetoresistance in metals was first worked out in detail by the Soviet scientists I. M. Lifshitz and V. G. Peschanskii.

2. Semiconductors.—Many experimental methods for metals (particularly cyclotron resonance) are used for semiconductors; measurements are not made of the Fermi surface, but of properties of conduction electrons and holes.

Piezoresistance.—The change in electrical resistance of a material when it is stressed is piezoresistance. In a single crystal the stress can be applied in different ways and the electric field can be applied in various crystallographic directions; appropriate combinations of these yield an array of piezoresistance coefficients for the material. In semiconductors the piezoresistance coefficients are usually much larger than are those of metals. Their measurement (first performed by C. S. Smith in 1954 for the semiconductors germanium and silicon) allows inferences about the location of excess electrons and holes in wave-vector space. Because of their large piezoresistance, small germanium wafers are extensively used as strain gauges.

Optical Absorption.—A semiconductor cannot absorb electromagnetic radiation unless the photon energy is sufficient to lift an electron across the energy gap. Information on minimum energy gap, the density of energy levels on each side of the gap, and other gaps between filled and vacant conduction bands can be obtained from measurements of the change in optical absorption as frequency of incident electromagnetic radiation is varied. Such measurements can be obtained from experiments in which a light beam is transmitted through or reflected from thin films of the material. Measurements of optical absorption have yielded information about the energy-band structure of valence semiconductors (*e.g.*, germanium, silicon, indium antimonide, and tellurium).

V. CRYSTAL IMPERFECTIONS

It has been noted that imperfections help determine some of the most important properties of crystals, including the electronic conductivity of semiconductors, the electrolytic conductivity of salts, and the plastic properties of all ductile materials. Before 1940 it might have been supposed that new imperfections would be introduced almost indefinitely to describe the properties of solids. However, by the 1960s it appeared that the complexity arises from a few types of imperfection that play an intricate role within the crystal. The principal imperfections seem to be the following.

1. Lattice Vibrations (Phonons).—Phonons have been identified as excitation units of lattice vibration propagating through and disordering a crystal. A random group of vibrational waves (such as might arise through heating the solid) may interfere with one another constructively and destructively. Thus phonons impart a large amount of energy to a single atom when constructive interference is appropriate. Such an event corresponds to a large thermal fluctuation, which may be enough to eject an atom from a normal position in the lattice or effect a similar change.

2. Free Electrons and Holes.—As mentioned, the ideal insulating solid is one in which an uppermost filled band is separated from an empty one by an appreciable energy gap. Such an insulator becomes conducting if free electrons are excited into the empty band to leave free holes in the filled band. The conductivity depends on the number of such electrons and holes and the ease with which each moves; in an otherwise perfect insulator they can be looked upon as a type of imperfection.

3. Excitons.—A hole and an electron in a given insulator have opposite charges and, as a result, attract one another in accordance with Coulomb's law (*see* ELECTRICITY: *Electrostatics*). Just as an electron and a proton in a hydrogen atom have bound states in which they rotate about a common centre, an electron and a hole can move as a closely coupled uncharged unit. Called an exciton, this unit can transport energy from one part of the crystal to another. The exciton can be viewed as being generated by putting the insulating crystal in an excited electronic state, similar to the discrete states of an atom which lie below the ionization limit. The exciton is relatively difficult to detect directly, being uncharged and not deflected easily by electric or magnetic fields. Excitons have been detected, however, in salts such as alkali halides and cuprous oxide. They probably are important in photochemical processes, particularly when energy associated with incident light mediates a chemical reaction at the surface of a crystal. In such cases the energy may be transferred by excitons from the interior (where the light was absorbed) to the surface.

4. Vacancies and Interstitial Atoms.—Thermal fluctuations may drive atoms from normal lattice sites into interstitial positions, producing vacant sites. Such imperfections can lead to even more disorder; *e.g.*, one of the atoms in a normal site neighbouring a vacancy may jump into the vacancy. Or an interstitial atom may replace a neighbouring normal atom by pushing it into another interstitial place. Such mechanisms give freedom of motion to the typical atoms of a lattice. The migration of thermally induced vacancies and interstitial atoms is responsible for diffusion and electrolytic conductivity in most solids.

Vacancies and interstitial atoms can be produced in pairs by bombarding a lattice with fast particles such as protons, neutrons, and electrons produced by high-voltage accelerators. The defects may also be produced by radioactive disintegration of atoms within the lattice, reflecting so-called radiation damage. Studies of such damage and its recovery illuminate the behaviour of interstitial atoms and vacancies in typical solids.

5. Foreign Atoms.—Atoms with loosely bound electrons or holes may transform an insulator into an impurity semiconductor. Similarly, appropriate foreign ions in ionic crystals may be accompanied by vacant lattice sites or interstitial atoms that become free at normal temperatures to increase electrolytic conductivity and diffusion. For instance, divalent ions such as Ca^{2+} replace two $Na+$ ions when dissolved in NaCl. The calcium ion occupies one site but the other is vacant and may become mobile.

Similarly, S^{2-} can be dissolved in silver chloride by substituting for Cl^-. The ion is accompanied by an Ag^+ ion in an interstitial site.

Extra electrons associated with foreign atoms in insulating solids usually absorb and emit their own characteristic frequencies of light. Thus such foreign atoms may absorb or emit radiation and make the crystal fluorescent (*see* LUMINESCENCE).

6. Dislocations.—Dislocations are the most intricate of the imperfections in the lattice; they were introduced earlier in this article to explain plastic flow in ductile solids. Those called edge dislocations also may act as relatively easy sources or sinks for vacancies or interstitial atoms. Such imperfections can be produced by thermal fluctuations at dislocations in the interior with the same ease as at the crystal surface. What is termed a screw dislocation can terminate at a ridge on the surface, and is an ideal catalyst for the growth of the crystal from solution or vapour. The regions where dislocations break through to the surface can be detected by etching the surface with appropriate reagents. The point of emergence becomes the centre of an etch pit.

7. Interaction of Imperfections.—Lattice waves (phonons) may interact with electrons and holes and affect the current flowing through a crystal. Similarly, appropriate impurity atoms may capture free electrons or holes produced by light or other excitation and prevent them from contributing to the current. When edge dislocations are forced to move (as in plastic flow) they apparently leave a trail of vacant lattice sites that can enhance atomic migration in crystals. Irregular dislocations, particularly those present after plastic flow, can capture free electrons and holes.

Negative ion vacancies in salts (which are positively charged) may capture free electrons and produce what can be regarded as new imperfections. These neutral units are termed *F*-centres. They alter the colour and many other properties of the specimens containing them. They may be introduced in controlled amounts by heating an alkali halide crystal (such as sodium chloride) in alkali metal vapour. An excess of metal is absorbed by the crystal but actually appears in such a form that some of the halogen ions are replaced by electrons. The vacant lattice sites necessary for *F*-centres can be produced in a number of ways; *e.g.*, by plastic flow or by irradiation with ultraviolet light or X rays.

When a photographic film is exposed to light, a latent image that can be developed chemically is formed in the grains of silver halide. The process appears to involve interaction of a large number of imperfections, and was described theoretically from the atomic point of view by R. W. Gurney and Mott in 1938. They postulated that incident light produces free electrons and holes that wander about the crystal. The electrons become trapped at imperfections, probably dislocations or possibly foreign atoms. The trapped electrons attract interstitial silver ions produced thermally and which are mobile at room temperature. Clusters of silver atoms formed by this union of electrons and interstitial ions constitute the latent image. Such specks of silver may catalyze the transformation of the entire grain into free silver when a developer is present. The deposition of silver atoms at dislocations in silver bromide has been demonstrated. It has also been shown that *F*-centres in the alkali halides will precipitate along dislocations if the crystals are held at a temperature favouring the formation of colloids.

VI. SOLID STATE ELECTRONICS

Applications of solid state physics are perhaps best exemplified in electronics. Semiconductor devices have had a heavy impact on the electronics industry; *e.g.*, by supplying miniature substitutes for conventional vacuum tubes. Such magnetic materials as ferrite-core inductances have replaced air-core inductances in many high-frequency applications with subsequent miniaturization. Permanent magnet materials have been developed; one of these, the elongated single-domain particle, had its origin in a theoretical study of magnetic domain structure.

1. Semiconductors and Rectifiers.—Recall that a semiconductor is a solid in which the occupied range of electron energy levels is separated from the unoccupied region by an energy gap sufficiently small that electrons can be thermally excited across it. The occupied range is called the valence band and the unoccupied region beyond the gap is called the conduction band. Excitation to create a free electron in the conduction band and a free hole in the valence band is usually termed thermal generation of a hole-electron pair. The electron and hole can collide and recombine.

The number of free charge carriers (hence the conductivity) can be greatly increased by including small amounts of suitable impurities when the semiconductor crystal is formed. These impurities can be donor atoms which furnish extra electrons to the energy level structure of the parent semiconductor, or acceptor atoms which remove electrons. For example, in the common semiconductors germanium and silicon the four valence electrons go into the valence band, and semiconduction in the pure material occurs only through thermal generation of hole-electron pairs. Pentavalent atoms (*e.g.*, phosphorus, arsenic, and antimony) are donors; when such an atom substitutes for germanium (or silicon) in the crystal, it contributes four electrons to the valence band and one to the conduction band. Trivalent boron, aluminum, and gallium are acceptors since each substituted atom contributes only three electrons to the valence band.

Extrinsic semiconductors (those in which conductivity is controlled by impurities) do not contain equal numbers of free electrons and holes; both types of charge carrier are present but the concentration of the minority carrier is usually negligible compared to that of the other. A semiconductor that contains donor atoms is called an N-type (or excess) semiconductor since conduction is primarily by free electrons in the conduction band. A semiconductor containing acceptor atoms is called P type, and conduction is primarily by holes. Most industrial and research applications are for extrinsic semiconductors.

Joining two semiconductors with different properties (or a metal and semiconductor) often produces a rectifying junction in which current is conducted most readily in one direction. One of these was the "cat's whisker" detector used in the early days of radio reception to rectify the feeble radio-frequency signal; it consisted of a metal wire making a point contact to a semiconductor (usually lead sulfide). Other early devices with larger current-handling capacity included copper oxide and selenium rectifiers. Known as barrier-layer rectifiers, they are more complicated in operation than the junction rectifier described below.

A P region and an N region in the same crystal produce what is called a P-N junction which functions as a good rectifier; such rectifiers made of silicon have largely replaced other types (except for high-voltage applications where vacuum diodes are superior; *see* ELECTRON TUBE).

Rectification in a P-N junction can be understood by reference to fig. 6. Two dissimilar substances brought into contact tend to come into equilibrium by exchanging heat and electrons. Equilibrium in terms of electrons is expressed by equality of the electrochemical potential (also called the Fermi level) in the two materials. In a semiconductor the Fermi level lies in the energy gap close to the valence band in a P type, and close to the conduction band in an N type. Fig. 6A represents energy-level structure at equilibrium; a few electrons in the conduction band can diffuse into the P region to combine with holes. Similarly a few holes can diffuse into the N region to combine with free electrons. both diffusion processes contribute current in the same direction. This is balanced by a thermally generated reverse current of electrons in the P region and holes in the N region (which move readily across the junction) and the net current is zero.

If the Fermi level in the N region increases by voltage V, as in fig. 6B, diffusion of electrons and holes over their respective barriers is increased; if the Fermi level drops diffusion is inhibited. In both cases thermal generation of electrons in the P region and holes in the N region is unaffected. The net current I through the junction is given by

$$I = I_o[\exp(qV/kT) - 1]$$

which leads to rectification when the voltage difference V across the junction is greater than kT/q. Here T is the absolute temperature, k is Boltzmann's constant, q is the electronic charge, and exp is the exponential function.

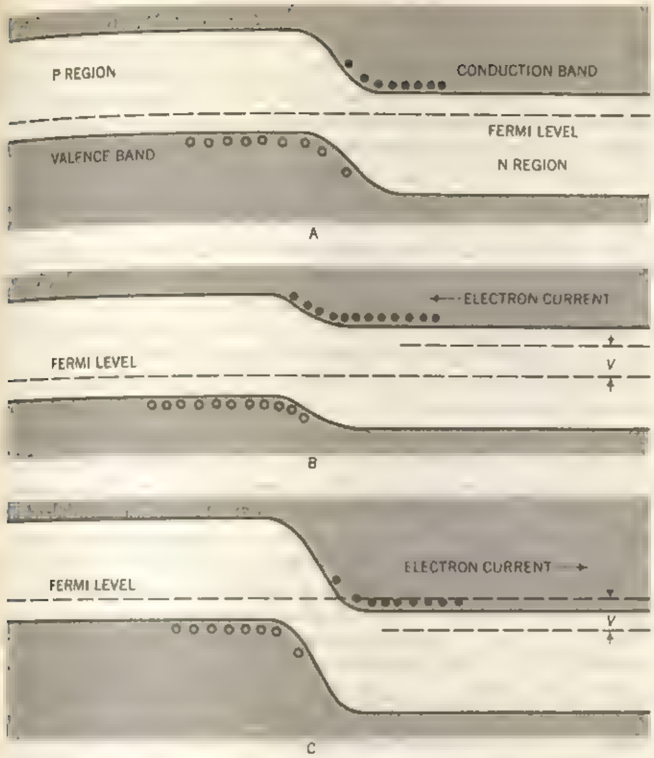

FIG. 6.—ELECTRON ENERGY LEVELS AT A P-N JUNCTION. BLACK DOTS REPRESENT ELECTRONS; CIRCLES REPRESENT HOLES
(A) Equilibrium; (B) forward voltage difference V applied across junction; (C) reverse V applied

To make practical devices some of the metallic contacts to the semiconductor must be nonrectifying. Metals with small work functions generally make nonrectifying (ohmic) contacts to N-type semiconductors while those with large work functions make rectifying contacts; the opposite is the case for P types. The work function of a metal is the minimum energy (usually expressed in electron volts) required to remove an electron from the surface of the metal.

Semiconductor crystals with more than one P-N junction are known as junction transistors and are discussed under TRANSISTOR.

2. Tunnel Diodes.—The tunnel diode is a two-terminal semiconducting device consisting of a single P-N junction, but its current-voltage characteristic is quite different from that of a conventional junction rectifier. The difference comes about through the inclusion of suitable impurities; the P and N regions are made highly conducting, their conductivity being about 1,000 times greater than that of the P-N junctions discussed above. This moves the Fermi level into the valence band on the P side, and into the conduction band on the N side, and under equilibrium conditions vacant levels on one side of the junction stand opposite filled levels on the other. Furthermore, the junction is quite narrow.

Under these conditions electrons can tunnel directly through the junction from occupied levels to vacant levels of the same energy on the other side. The phenomenon cannot be understood in terms of classical physics; it is a quantum mechanical effect intimately associated with the wavelike properties of the electron.

The forward characteristic of the tunnel diode is shown in fig. 7. As the Fermi level of the N region is raised relative to that of the P region through application of external voltage, more vacant energy levels on the P side are brought into coincidence with the filled conduction levels of the N region, and the tunnel current increases. If the forward bias is increased beyond a certain value (approximately 0.05 v. in germanium) the levels on opposite sides of the junction move out of coincidence, and the tunnel current drops. This decrease in current as voltage increases is generally called a negative-resistance or negative-conductance characteristic; in other words, an incremental increase in voltage produces an incremental decrease in current through the device. As forward bias is further increased, the normal rectifier characteristic takes over.

Because of its negative-conductance region, the tunnel diode can be used in electronic circuits to produce amplification or oscillation. The device has replaced transistors in many applications, offering the advantages of extremely high-frequency operation, small size, low noise, low cost of manufacture, and high reliability.

3. Photoconductors and Xerography.—Materials that lose electrical resistance when subject to illumination are photoconductors. The phenomenon is most striking when the unilluminated material has low conductance, since the mobile carriers created through absorption of light quanta can then produce a drastic reduction in resistance. A good photoconductor is usually an intrinsic semiconductor; each photon (light quantum) absorbed by the material excites an electron across the energy gap to create an electron-hole pair.

One of the more interesting applications is that of xerography, a photocopy process. If the photoconductor has a large enough resistance in the dark, it can store charge for appreciable periods of time; *e.g.*, amorphous selenium with a dark resistivity in excess of 10^{11} ohm-cm. can store charge for seconds. If a thin layer of photoconducting material is charged electrostatically and then illuminated with a focused or projected image, the bright regions become electrically conducting and discharge. After the illumination is removed, the photoconductor can be dusted with a frictionally charged powder that adheres to the remaining surface charge. The photoconductor thus carries a powder reproduction of the original image which can be transferred by contact to paper, and fixed by heat to provide an inexpensive photocopy. Since some of the powder tends to remain on the paper, a number of copies of the same image can be made. Commercially available xerographic equipment can reproduce information with a resolution in excess of 10 lines per millimetre at a speed of about 1,200 linear feet per minute.

4. Solar Batteries.—In the vicinity of a P-N junction the electron and hole in a pair are separated by the strong electrostatic field; electrons move into the N region and holes into the P region. Hole-electron pairs are thermally generated in small numbers at all times and contribute to the reverse current through the junc-

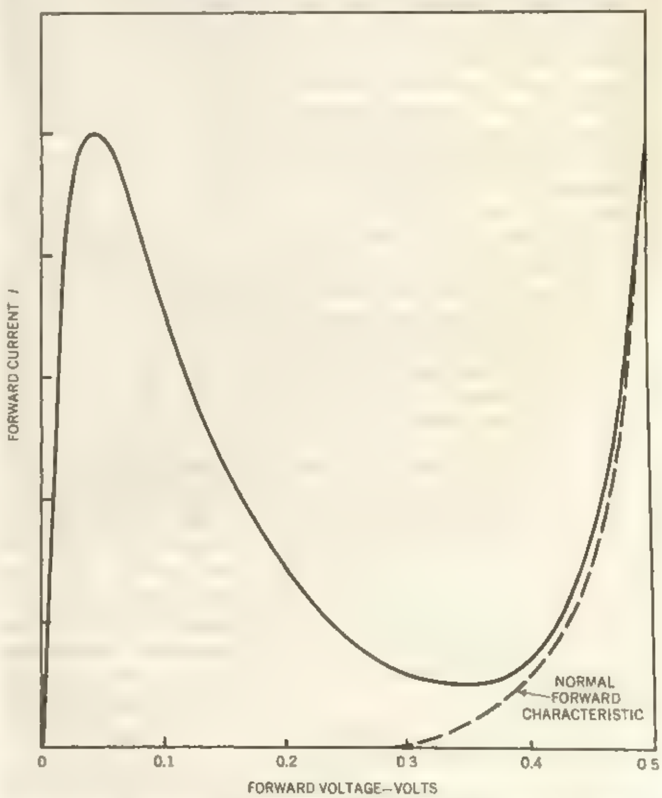

FIG. 7.—CURRENT-VOLTAGE CHARACTERISTIC OF A TUNNEL DIODE

tion; but if many pairs are created by absorption of light, the equilibrium of the junction is disturbed and the P region develops a positive potential relative to the N region. In other words, the P-N junction becomes a battery when illuminated.

The circuit may be completed by joining the P and N regions through an external load. The illuminated junction generates current continuously, and power is dissipated in the load. Photovoltaic conversion efficiency in such a device principally depends on width of energy gap in the semiconductor relative to photon energy in the incident radiation. Silicon cells have a theoretical conversion efficiency of about 20% for solar radiation; commercial cells with efficiencies greater than 12% have been constructed.

Solar batteries were found to be quite reliable in early U.S. space satellites (*see* SPACE EXPLORATION: *Typical Spacecraft*). They are also used as low-power generators for remote earth-based locations where climatic conditions permit their use.

5. Thermoelectric Materials.—Important applied thermoelectric effects are conversion of heat energy into electricity (thermoelectric power generation), and the use of electrical energy to maintain temperature below the ambient level (Peltier cooling or refrigeration). The efficiencies of both processes depend on the temperature interval and on certain material parameters. Theoretical analysis has shown that the important combination of material parameters is $\alpha^2/\rho\kappa$, where α is the Seebeck coefficient, ρ is electrical resistivity, and κ is thermal conductivity. The Seebeck coefficient is defined as the thermoelectric voltage developed by the material for a 1° C temperature difference (*see* THERMOELECTRICITY).

The best thermoelectric materials appear to be extrinsic semiconductors with carrier concentrations in the range of 10^{19}/cc. However, there are important differences among semiconductors, and the development of useful materials required substantial research. Modest conversion efficiencies are possible with the semiconductors: bismuth telluride or lead telluride. In the 1960s much effort was being devoted to study of high-temperature semiconducting oxides.

SOLIHULL, a county borough in Warwickshire, England, 8 mi. (13 km.) SE of Birmingham on the road to Warwick, and on the main Birmingham–London Railway. Pop. (1961) 95,977. Solihull grew rapidly after the 1920s from an urban district in 1932 (pop. 25,373) to a municipal borough in 1954 (72,000). It became a county borough in 1964, and includes Shirley, Olton, Sheldon, Elmdon, Knowle, and Dorridge. The parish church of St. Alphege, with its 13th-century chancel, is the most important old building. Others include Packwood House (15th century), owned by the National Trust, with a unique yew garden. Solihull public school was founded in 1560. Though mainly a residential area, Solihull has automobile and other light industries. (W. M. ML.)

SOLIKAMSK, a town in Perm *oblast* in the Russian Soviet Federated Socialist Republic of the U.S.S.R., stands on the small Usolka River, 7 mi. above its confluence with the Kama. Pop. (1959) 82,874. The town, probably the first Russian settlement in the Urals, was founded in the early 15th century as a salt-mining centre and it has remained so to the present. Its deposits of potassium salts are among the world's largest. The important chemical industry based on them produces fertilizers, chlorides, bromide, sulfides, and industrial alcohol. The magnesium works are the largest in the U.S.S.R. A railway and highway join the town to Berezniki on the Kama.

In 1959 the satellite town of Borovsk was merged with Solikamsk. (R. A. F.)

SOLIMAN: *see* SULEIMAN I; SULEIMAN II.

SOLINGEN, a town of West Germany in the *Land* (state) of North Rhine-Westphalia, Federal Republic of Germany. One of Europe's oldest centres for the manufacture of cutlery, it is equaled in importance only by Thiers, France, and Sheffield, Eng. Pop. (1961) 169,930. The town lies on the Wupper River, 17 mi. (27 km.) E of Düsseldorf, and the centre, severely damaged by bombing during World War II, has been rebuilt with wide streets and parks. The craft of making swords was established in Solingen in the Middle Ages and was still carried on in the mid-20th century. Cutlery, widely exported and chiefly produced in small- to medium-sized factories, accounted in 1965 for about 25% of the town's industry. Metallurgical industry predominates (machine tools, tubes, foundries); the remainder ranges from chemicals to sweets. Much of Solingen's immediate surroundings are forest and farmland. Chartered in 1374, the town was enlarged in 1929 to include Ohligs, Wald, Gräfrath, and Höhscheid. A museum at Gräfrath illustrates the development of cutting implements and cutlery from prehistoric to modern times. Solingen is connected to the Cologne-Ruhr Autobahn and the Cologne-Wuppertal railway, which pass west of the city centre.

SOLIPSISM (Latin *solus*, "alone," *ipse*, "self"), in philosophy, a term originally applied to moral egoism (*q.v.*) but now used in an epistemological sense to denote the extreme form of subjective idealism which denies that the human mind has any valid ground for believing in the existence of anything but itself. F. H. Bradley, in *Appearance and Reality*, characterized the solipsistic view as follows: "I cannot transcend experience, and experience is *my* experience. From this it follows that nothing beyond myself exists; for what is experience is its (the self's) states." Presented as a solution of the problem of explaining our knowledge of the external world (*see* KNOWLEDGE, THEORY OF), it is generally regarded as a *reductio ad absurdum*. *See* further IDEALISM; and compare PHENOMENALISM.

SOLÍS, JUAN DÍAZ DE (1470?–1516), Spanish navigator and one of the early explorers to enter the Río de la Plata estuary. As a pilot major of Spain he led an expedition which left Sanlúcar de Barrameda, Spain, on Oct. 8, 1515, in three ships. After touching the coast of modern Brazil around Cape São Roque, he sailed down the east coast of South America and in January 1516 reached the Río de la Plata (River Plate), which he called Mar Dulce. He entered the estuary and named the first island he found Martín García after one of his sailors who had died. Sailing partly up the Uruguay River, he landed with eight men on the left bank, in modern Uruguay, inhabited at the time by the Charrúa Indians, who attacked his party while they were taking possession of the land for Spain. All but one were killed and eaten by the Indians in sight of the remaining crewmen on the ships. Francisco del Puerto, the sole survivor, was made prisoner, and later gave valuable information about the area to Sebastian Cabot when he arrived in the region in 1526.

The ships sailed back to Spain, but one was wrecked off the island of Santa Catarina near the south coast of Brazil, and 11 of the crew saved themselves by swimming ashore. Survivors of this group were rescued by Sebastian Cabot and told him of great wealth in the interior of South America. Cabot, as a result, sailed south, entered the Río de la Plata and ascended the Paraná River looking for the kingdom of silver. After 1948 Argentine historians accepted the contention of their colleague (Roberto Levillier) that Amerigo Vespucci and not Solís discovered the Río de la Plata, as early as 1502. (F. L. HN.)

SOLITAIRE, the name given to certain American birds of the thrush family (Turdidae) and to an extinct flightless bird. The present-day solitaires (*Myadestes* and *Cichlopsis* species) are noteworthy songsters. The best known is Townsend's solitaire (*M. townsendi*), found in the Rockies from Alaska to northern Mexico; it is a slim gray bird with a white eye-ring, white sides of the tail, and a buffy wing patch.

The extinct solitaire (*Pezophaps solitaria*), which formerly lived on the island of Rodrigues, was exterminated, along with the closely related dodos, by man and introduced animals (*see* also Dodo).

SOLITAIRE is the preferred name in the United States for all games of patience, or card games that may be played by one person. There are more solitaires than all other card games together, and solitaire is the most widely played of all forms of cards.

Most games are played with one or two 52-card packs, the cards ranking king (high), queen, jack, 10, 9, 8, 7, 6, 5, 4, 3, 2, ace. Sometimes the sequence is continuous, the ace ranking next to the king. Many solitaire games are known by a variety of names; even the game probably played by most players, Klondike, is more often miscalled Canfield, properly the name of a quite different game. The following terms describe features common to most games:

1. *The layout.*—The array of cards as first dealt on the table, comprising all cards that do not remain in the hand.
2. *The tableau.*—A distinctive arrangement into which the cards that may be "worked" are first dealt.
3. *The foundations.*—Usually all the cards of a designated rank, upon which other cards are built in sequence.
4. *The stock.*—A special pile of cards that is part of the layout in some games.
5. *The hand.*—Any remainder of the pack not used in the layout.
6. *The talon.*—A waste or discard pile into which are placed those cards turned up from the hand that cannot be immediately built upon the tableau or foundations.
7. *Available Cards.*—Those cards of the tableau, stock, etc., that are subject to transfer to other parts of the layout. In most games, certain cards of the tableau are not available until uncovered by the transfer of cards above them.
8. *A space.*—An empty place in the tableau created when all the cards of one pile have been transferred elsewhere.
9. *Rows.*—Lines of cards across the table horizontally.
10. *Columns.*—Lines of cards extending vertically away from the player.

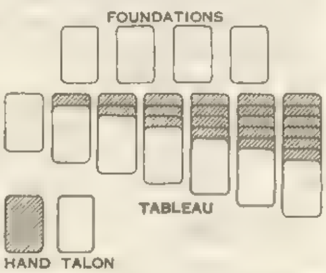

FIG. 1.—LAYOUT OF CARDS FOR KLONDIKE

A few of the popular forms of solitaire are here described.

Klondike.—One pack is used and a tableau dealt of seven columns in a row, with one card in the column at the far left, two in the next, three in the third, etc., the column at the far right containing seven cards. Only the topmost card in each column is turned face up. The foundations are aces, which are put in a row above the tableau as soon as they become available. Each foundation must be built up in the same suit in sequence to the king (*i.e.*, ace, deuce, trey, etc.). A card placed in a foundation may not thereafter be moved.

On the uppermost card of any tableau pile may be placed a card of next lower rank and opposite colour. When transferring cards within the tableau, all the face-up cards on any tableau pile must be moved as a unit onto a card of next higher rank and opposite colour to the highest card of the unit. If the highest card of the unit is a king, it may be moved only into a space, and a space may be filled only by a king (or a unit built upon a king). The lowest card of a unit may be removed and played in proper sequence upon a foundation pile.

Whenever a transfer leaves a face-down card uncovered, this card is turned up and becomes available.

The hand is turned one card at a time and is run through once only. A card not added to the foundation or the tableau is placed face up on the talon. Top card of the talon is always available.

Game is won if all cards can be built upon the foundations.

Double Klondike.—Many solitaires can be played by two, but Klondike is by far the favourite for this purpose and is the game referred to as double solitaire. Each player deals his own layout with his own deck. Neither may build on the other's tableau, but foundation piles are common property. Turn to play alternates, ending when a player lays a card on his waste pile. Play continues until one player has built all his cards on the foundations or until neither can make a further play. It is not compulsory to play a card to the centre; strategy may dictate withholding a play that would help the opponent get rid of a great number of cards.

In a blocked game, winner is determined by counting the cards each has played to the foundations.

Canfield.—From a single pack, a stock of 13 cards is counted out and the pile turned face up, with only the top card visible. The next four cards are dealt face up in a row to the right of the stock, forming the tableau. The next card is placed face up above the tableau to start the foundation row. Other cards of the same rank as this starter are placed in the foundation row as soon as available. Foundation piles are built in continuous ascending sequence in the same suit. (Thus, with ♡Q turned as the starter, other queens are played to the centre as soon as available. After the king has been added, the next card in sequence is the ace, then the 2, 3, etc.)

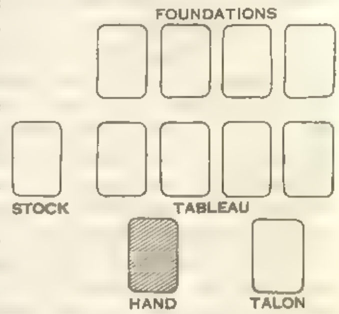

FIG. 2.—CANFIELD

Tableau columns are built in downward sequence and alternate colour, black on red, red on black. The king plays on the ace unless either rank is the foundation starter. Piles may be combined when the touching cards are of correct sequence and colour. Customarily, the entire column must be moved as a unit but some play that the available card may be individually shifted; *i.e.*, a column of ♡ 8, ♤ 7, ◇ 6 may be placed as a unit upon the ♤ 9 or ♧ 9, or the ◇ 6 may be shifted separately onto ♧ 7 if available, after which ♤ 7 may be placed on ◇ 8.

The hand is turned up in packets of three cards at a time, each packet being placed face up on the talon. The top card only of the talon or stock is available; the card immediately below becomes available when the top card is played. A space must be filled by the top card of the stock, but when the stock is exhausted the player may use any available card of the talon.

After the hand is run through once, the talon is turned over and, without shuffling, is run through again, continuing as often as plays can be made. Game is won if all cards are played onto the foundations.

Others.—The wide variety of solitaire games offers simple layout and count-out pastimes suitable for children, such as clock and accordion, as well as games that are a challenge to skill, such as calculation. Few who know how to play cards of any kind do not know at least one kind of solitaire.

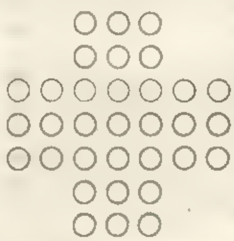

FIG. 3.—ARRANGEMENT OF HOLES FOR VERSION OF PEGBOARD GAME

Pegboard Game.—Solitaire also is the name of a pegboard game or solo puzzle, similar to a game the American Indians played with arrows stuck into the ground. In one version, the board is pierced with 33 holes arranged in a pattern of three vertical and three horizontal rows intersecting to form a cross. Pegs are set in all but one hole. One peg at a time is jumped over another and into a vacant hole, the peg thus jumped being removed from the board as in checkers. Jumps must be horizontal or vertical, never diagonal; the object of the basic puzzle is to remove from the board all but a single peg.

To make the game even more difficult, one variation calls for the last peg to be left in the centre hole.

See Morehead and G. Mott-Smith, *Complete Book of Solitaire and Patience Games* (1949). (R. L. Fy.)

SOLNA, an industrial suburb 3 mi. N.W. of Stockholm, Swed. Pop. (1960) 50,864. It is an ancient settlement and antedates Stockholm, having historic buildings including an 11th-century church and old palaces and manors. Ulriksdal palace on Lake Edsviken is the royal residence for part of the year; the Haga palace on Lake Brunnsviken is the crown prince's residence; and the Karlberg palace is now the Royal Military school.

There are also a Nobel institute for scientific research, an institute for the blind and the Karolinska hospital with a medical school. Sports facilities include a racecourse and football stadium. Its expanding industrial development includes printing works and electronic industries. It is also a centre of the Swedish film industry. (L. E. MA.)

SOLO (BENGAWAN), a river (*Kali*) in East Java, Indonesia, and the longest river (335 mi.) of Java. Its headwaters are on the slope of the Lawu volcano and the southern limestone range (Gunungkidul). Flowing through several small basins the river enters the densely populated Surakarta plain near Wonogiri. Several tributaries join it in this volcano-bordered plain. North of Surakarta (or Solo) the river gradually bends eastward round the central limestone range (Gunungkendeng). Its longest tributary, the Madiun, joins the Solo at Ngawi, where it begins its 20 mi. breakthrough of the Gunungkendeng and emerges into the region called the Solo valley. There the river has little gradient and meanders through a lowland 10 mi. wide and 80 mi. long between the Gunungkendeng and the northern limestone ridges in the district of Bodjonegoro.

A project to use the Solo river for large-scale irrigation was never completed. The delta is very marshy and used for fish ponds. In order to reduce silting of the strait between Madura and Java (the northern approach to the port of Surabaja) the main mouth of the Solo was diverted to the north, away from the strait.

In the dry season much of the river bed is dry; in the wet season (November–April) the average volume (in the Solo valley) is 440 cu.m., the maximum 2,800 cu.m.

The Solo is navigable for river *prahus* (fishing boats) from Ngawi downstream. Sea-going *prahus* in the wet season can reach Tjepu. *See* JAVA: *Archaeology* for an account of hominid remains in the region of the Solo river. (J. O. M. B.)

SOLOGNE, a district of central France contained within the great northward arc of the Loire river toward Orléans. It lies mainly in the *départements* of Loiret and Loir-et-Cher, with a southeastward extension into Cher, and is a flat area (*c.* 200 sq.mi.), covered with thick deposits of debris brought down from the crystalline rocks of the Massif Central.

The resultant soils, extremely deficient in lime, are very infertile, and the clays hold up water in slight hollows so that the countryside is studded with innumerable meres and ponds. Sluggish westward-flowing streams, the Sauldre, Beuvron and Cosson, traverse it toward the Loire.

For centuries Sologne remained a backward area, where poor crops of rye and buckwheat were grown on widely scattered farms, and most of the country was left in a wild state of woodland, marsh and water, devoted to the chase and owned in large estates surrounding châteaux, such as Chambord.

Reclamation for agriculture, undertaken after the middle of the 19th century, has made some headway, with drainage works and use of fertilizers, but there are large game preserves and buckwheat is still cultivated for pheasants. Generally a *polyculture* (mixed farming) is practised and poultry and dairy cattle are kept. The ponds, stocked with fish, and the woodlands play their part in the local economy.

The population is still sparse, and is served by market towns such as Gien, Orléans and Blois in the Loire valley, and Romorantin and Vierzon on the southern borders. (AR. E. S.)

SOLOGUB, FEDOR (pseudonym of FËDOR KUZMICH TETERNIKOV) (1863–1927), Russian Symbolist poet, novelist, and playwright, was born at St. Petersburg on Feb. 17 (Old Style; March 1, New Style), 1863. His father, a tailor, died when Sologub was quite young, and his mother's employers paid for his education. He became a teacher, and, finally, a superintendent of elementary schools, retiring in 1907. His first volumes of stories and poems and his first novel, *Tyazhelye sny* ("Bad Dreams") were published in 1896. As a poet, he became a leading representative of Russian Symbolism, combining classical limpidity of form with modernist, even "decadent," content. His work reflects a dualistic, Manichean view of life. His best and most successful novel is *Melkii bes* (1907; "The Petty Demon"; first trans. as *The Little Demon*, 1916). Also interesting and characteristic is the ambitious trilogy *Tvorimaya legenda* (1908–12; partially translated as *The Created Legend*, 1916). Sologub also wrote plays, and many highly original stories, some of which are translated in *The Old House and Other Tales, The Sweet-scented Name, and Other Fairy Tales, Fables, and Stories* (both 1915), and *Little Tales* (1917). He took a sharply negative attitude toward the Bolshevik Revolution of 1917, and, after his wife's tragic suicide in 1922, withdrew into himself. Much of the poetry of his last years remains unpublished.

Sologub died in Leningrad on Dec. 5, 1927.

SOLOLÁ, a department in the central highlands of Guatemala and location of the beautiful Lake Atitlán. Area 410 sq.mi., of which 53 sq.mi. are covered by the water of the lake; pop. (1964) 108,815. The lake and town of Atitlán (*q.v.*), a favourite tourist area, occupies a valley dammed by volcanic ash at an altitude of about 4,900 ft. On the borders of the lake are three cone-shaped volcanoes, Atitlán, Tolimán, and San Pedro.

The Maya Indians, who make up the greater part of the population, grow maize, wheat, and beans. On the southern shore of the lake there are plantations of coffee. Much land in the department is used for the feeding of beef cattle and hogs. The lake is also used for fishing. The department is served by the Inter-American Highway which passes through Sololá on the way from Guatemala City to Quezaltenango.

Sololá, the departmental capital (pop. [1964] 21,382 [mun.]), is near the northern shores of the lake, about 45 mi. WNW of Guatemala City. It is 6,900 ft. above sea level. It is a colourful market centre for the Indian farmers of the highlands who come to buy or sell cotton and woolen textiles and foods. (P. E. J.)

SOLOMON (d. *c.* 934 [922] B.C.), the second king of the united Judah-Israel and the wise man par excellence in the Bible and in folklore. He succeeded his father, David (*q.v.*), *c.* 974 (or, according to those who favour the later chronology, *c.* 962) B.C. and reigned for 40 years. According to the lists of I Chron 3:5 and 14:4 he was the fourth son born to David in Jerusalem. Solomon ("peace," "prosperity") was the name his parents gave him, but Nathan the prophet called him Jedidiah ("beloved of the Lord"). He became king through a carefully planned plot by Nathan, swiftly carried out by Nathan and Bathsheba. When Adonijah, David's oldest surviving son, attempted to seize the throne in David's old age, Nathan acted with all speed, persuaded the aged king that he had promised the succession to Bathsheba's son, and led him himself to institute Solomon. In course of time Solomon astutely managed to eliminate Adonijah and his supporters without incurring blood guilt.

The picture of Solomon as painted by the compiler of I Kings 1–11 is previewed by the story of the young king's visit to the shrine at Gibeon (3:4–15), when Solomon asked not for riches and honour but for wisdom to be a good judge and ruler, with the result that he was granted all three. The rest of the account of Solomon's reign from 3:16 to the end of ch. 10 is designed to show the fulfillment of this promise, and it is done most thoroughly. All the untoward events of Solomon's reign are relegated to the last chapter (11), with the result that they are placed in decidedly low relief. The account of Solomon's reign in II Chron. 1–9 gives an even more impressive picture of peace and prosperity since the splendour of the Temple buildings is emphasized and all reference to rebellions and reverses is entirely omitted.

The King and His Successes.—The first ten chapters of I Kings undoubtedly convey the intended impression that Solomon's

reign was prosperous and peaceful and that he himself was wisest of the wise, richest of the rich. He married "the daughter of Pharaoh" and thus formed an alliance with Egypt. This marriage brought him the further gain of Gezer, a Canaanite fortress which the Hebrews had never been able to capture. The pharaoh had taken and reduced it, and he gave it to Solomon by way of dowry. Solomon rebuilt and fortified the city in company with numerous others which were used as barracks, arsenals, and storehouses. Even more advantageous was the extension of the treaty which David had made with Hiram, ruler of the Phoenician city of Tyre. In partnership with him, Solomon maintained a fleet of oceangoing ships, some possibly trading in the Mediterranean but others certainly sailing from Ezion-geber, a port on the Gulf of Aqaba, close by the modern Israeli port of Elath. These ships made three-year voyages and brought back "gold, silver, ivory, apes, and peacocks." The word *tukkiyyim* ("peacocks") is generally held to be the Malabar word, and the word for "apes" (*qophim*) is still in use on the Malabar coast, so presumably these eastern voyages extended at least as far as southwestern India. Perhaps that was the site of Ophir, with which Hiram traded, unless it was Ceylon, or perhaps even beyond to the Spice Islands (the Moluccas in Indonesia). It is evident that the treaties with Tyre and Egypt brought Israel for the first time fully into the current of Oriental commerce. Solomon's court was justly famed for its wealth and magnificence. The climax of the story comes with the visit of the queen of Sheba, rich and beautiful, who was astounded at what she saw. "There was no more spirit in her" (it took her breath away; II Chron. 9:4).

The long reign of Solomon, his wealth, and the temporary weakness of all neighbouring kingdoms enabled him to indulge his passion for building. He spent 13 years in constructing a splendid royal dwelling and with it a complex of buildings, including, above all, the Temple. This Temple was actually an appanage to the palace, built after the Phoenician style, and many of the symbols in it were of foreign origin: the two pillars before the entrance, the brazen "sea" and the palm and pomegranate decorations. Later days made the Temple the very centre and inspiration of Israel's life and devotion, and for this reason the description of it occupies a considerable place in the records. This is right and proper, because it was the writer's justification for extolling the deeds and splendour of Solomon the magnificent, Solomon the wise, Solomon the builder of the Temple. (*See* also TEMPLE, JEWISH.)

The King and His Difficulties.—In I Kings 11 the other side of the picture appears. The writer kept it to the last so that it appears to be only in Solomon's last years that things went wrong. Apparently Solomon's building of temples was not confined to that on Mt. Zion. He built at least one heathen temple on the Mount of Olives, east of and opposite to the Temple mount. He made provision for the worship of the many deities of his many wives and concubines. This is said to have taken place when he was old, but it must have been much earlier. Many untoward things happened comparatively early in his reign. After the death of Joab (11:21; this was early in the reign) the Edomite prince Hadad, who as a child escaped the ruthless massacre of the Edomites, returned and ruled in Edom. The Aramaean Rezon established himself in Damascus. These two events robbed Solomon of his command of the overland trade routes. He had to cede territory in Galilee to pay his debts to Hiram of Tyre (9:12–14).

There were troubles within the kingdom. In order to obtain supplies for his grandiose schemes, Solomon divided the country outside Judah into 12 districts, independent of the old tribal divisions. One month's supply was exacted from each district in turn. It is declared (9:20–22) that the Israelites were not treated as "bond servants" and that the forced labour needed for the building projects was exacted from the Canaanites, but it is plain that the labour levy was exacted from all Israel (*i.e.*, the northern tribes) and that all except the men of Judah were forced to work in the Lebanon for one month in three. Apparently the north was subject to the south; it was far from being an equal partnership. Jeroboam son of Nebat was in charge of "all the forced labor of the house of Joseph" (11:28). He raised a revolt against Solomon and had to seek refuge in Egypt, but he returned at Solomon's death to reign over the northern tribes, who refused any longer to suffer the exactions of a Judaean ruler.

However splendid the court may have been, the common people must have been far from happy. The king's lavish expenditure was a primary cause of the discontent which led to the breakup of the kingdom under his successor. His expenditure was far too great for his resources. He lost territory he could not afford to lose and with it considerable revenue. He oppressed the northern tribes both in labour and in taxes. Doubtless he uttered many wise sayings, enough to make him the father of wisdom, so that all subsequent wise sayings were ascribed to him. But he was not a wise ruler; he dissipated all that David had gathered, threw away all that David had gained.

Solomon as a Wise Man.—Solomon's shrewdness as judge is illustrated by the story of the two harlots, one of whom killed her baby by lying on it and took instead the live baby of the other (3:16–28). The motif of the story, whereby the king uses the power of mother love, by suggesting that the surviving baby should be divided between them, to show to whom the living baby belongs, is a common element in folk stories in many lands. It may well be that this particular story is an adaptation from folklore, especially since there is an Arabian story of the 11-year-old Solomon giving a wiser judgment than his father in a case of damage by trespass. Such a borrowing is also likely in the famous story of the queen of Sheba. In Arabic literature she is held to be Bilkis (or Maqeda), the daughter of the jinn, more beautiful than the houris of paradise. There are many legends concerning her and Solomon, including the ancient tradition that her son by Solomon was the ancestor of the present-day royal house of Ethiopia.

Jewish and Muslim writings, notably the Talmud and the Koran, contain many stories concerning Solomon. According to Jewish tradition, he had a magic carpet 60 mi. long and 60 mi. wide, and could set off at dawn, breakfast in Damascus, and sup in Media. During one journey he was reproved for his pride by the queen of the ants. Solomon had a magic ring, engraved with the name of God. It contained four jewels, given him by four angels in the shapes of a whale, an eagle, a lion, and a serpent. These four jewels gave Solomon power over various parts of nature. That given him by the eagle-angel gave him dominion over animals and birds, and the whole ring gave him power over spirits and animals, wind and water. It is also said that the seal of Solomon was a six-pointed star (shield of David; *see* MAGEN DAVID), though Western legends make it the five-pointed "pentacle," the "Druid's foot" (*Drudenfuss*) which protected Faust's threshold so that Mephistopheles could not cross it. Solomon's throne had mechanical figures of animals and birds on each step, from the ox on the first step, which held out its foreleg for the mounting king to lean upon, to the eagles on the sixth step, which raised him and placed him on his throne. Muslim tradition says that once he lost his magic ring, that the rebel angel Sakhr obtained it and ruled as king for 40 days while Solomon wandered about ragged and destitute; but Sakhr lost the ring in the sea, and Solomon recovered it from the inside of a fish that had swallowed it. Once Solomon made a pilgrimage to Mecca on his magic carpet, sheltered from the sun by a canopy of birds. The hoopoe only was missing, and it was he, to save himself punishment, who told Solomon about the beauty of Bilkis. There is a story that Solomon employed the jinn to complete the Temple; he died before they finished, but his death was concealed from them by God for a year because he died standing at prayer and his staff supported him, dead but upright, till the work was finished, and the jinn did not know.

Solomon's reputation for wisdom caused the authors of various works of wisdom literature to claim his name. Among these works are three biblical books: Proverbs, Ecclesiastes, and the Song of Songs or Song of Solomon; one book of the Apocrypha, the Wisdom of Solomon, or Book of Wisdom; and two pseudepigraphal Jewish books, the Psalms of Solomon and the Odes of Solomon.

and KINGS, BOOKS OF THE. For Muslim and other stories of Solomon see E. A. Wallis Budge, *The Queen of Sheba* (1922); L. Ginzberg, *The Legends of the Jews*, vol. iv (1913). (N. H. S.)

SOLOMON, ODES OF, is a collection of 42 short pseudepigraphical hymns resembling the canonical Psalms in their general nature. They are characterized by a spirit of adoration; only exceptionally do they touch some theological theme, and then the religious lyric tends to veil it, wrapping it in mystical speech. But not everything fades away from our sight: the centre of salvation is not the cross but God's self-humiliation (as in Phil. ii); virginity is a prerequisite for perfection, and the congregation is envisaged as a mystical union.

Until 1908, when a Syriac manuscript containing both the Odes and the Psalms of Solomon was discovered, they were known only from fragments: a citation of one ode (xix, 6) in Lactantius' *Divinae Institutiones* (early 4th century A.D.); and five odes (i, v, vi, xxii, xxv) in the *Pistis Sophia*, a 3rd–4th-century Gnostic work in Coptic. One ode (xi) in Greek has subsequently come to light in a 3rd-century papyrus.

The question of provenance has been much discussed. The idea that the odes stem from Gnosticism is untenable; dualism is lacking and there is nothing else in them that indicates a Gnostic background. Nor are there any reasons for postulating a Montanist origin. These texts reflect the oriental Christianity of the 2nd century and are not unorthodox. Greek has been regarded as their original language, but their content—an amalgam of covenant consciousness, baptismal imagery and Encratism—indicates that their home must be sought in Mesopotamia. There seems to be an echo of the history of Edessa, the home of Syriac literature, and the style and rhythm savour of a Syriac original, which shines through even in the Greek version. Syriac provenance also would explain some affinities with the Thanksgiving Psalms found at Qumran (*see* DEAD SEA SCROLLS).

SOLOMON, PSALMS OF, a collection of 18 pseudepigraphical psalms extant in Greek and Syriac versions. The ascription to Solomon, which probably goes back to the editor who first put them into their present form, makes them analogous to the canonical psalter ascribed to David. The poet (or poets) who composed the Psalms of Solomon seems not to have thought of ascribing them to Solomon, for they contain not even an allusive reference to him. It makes little difference whether more than one author is concerned, for the psalms all come from the same period and milieu and share the same religious and political views. The most that can be said is that the three great political psalms (ii, viii and xvii) were written by one and the same author, a man of poetic vigour and imagination.

The Hebrew original of the Psalms of Solomon is not extant, but the Syriac translation as well as the Greek seems to have been made directly from it. This is indicated by a number of passages in which the Greek is incomprehensible because the Hebrew it translated must have been corrupt, whereas the Syriac reveals the correct reading in the Hebrew. (The reverse situation also occurs.) Only occasionally did the Syriac translator correct himself by reference to the Greek version.

The Psalms of Solomon were clearly composed in Palestine, and some certainly originated in Jerusalem. This accounts for the important role which Jerusalem plays in them. The three political psalms can be dated fairly exactly because they make a clear reference to Pompey the Great. Thus most of xvii was composed shortly before Pompey entered Jerusalem in 63 B.C., though verses 11–14 are a later addition which refer back to this event and date from after 61 B.C. In ii, 26 ff. there is a reference to the death of Pompey in 48 B.C. As all the psalms belong to the same period, the collection can be dated to between 80 and 40 B.C.

The importance of the Psalms of Solomon lies chiefly in their vivid and contemporary presentation of the political and religious thought of the "pious of Israel" (*i.e.*, the Pharisees) in the last century B.C. The author of the psalms was certainly a Pharisee. Psalm xvii is particularly interesting for its detailed description of the eschatological messianic king and the political and religious expectations of his reign. This is the conception of the Messiah still current among the Jews during Jesus' lifetime; as the Gospels show, it lies behind the reaction of the common people to Jesus' teaching, the opposition of the Pharisees, high priest and scribes, and the hopes and expectations of the disciples.

SOLOMON, SONG OF (or SONG OF SONGS; in the Douai version of the Bible, CANTICLE OF CANTICLES, from *Canticum Canticorum* in the Vulgate; derived from the title in the Hebrew Bible, SHIR HASHIRIM), a book of the Old Testament, one of the Megilloth, or "Rolls," the others being Ruth, Lamentations, Ecclesiastes and Esther. The Megilloth are read in the synagogue at certain festivals, the Song of Solomon being used at Passover, which celebrates the Exodus from Egypt. The reasons for this are not entirely clear, but the fact that spring is referred to in ii, 11 ff. and vi, 11 (Passover being also celebrated in spring), and the allegorical interpretation of the book as referring to God's love for Israel and the events of the Exodus, especially the Covenant at Mt. Sinai, should be considered in this connection.

Contents.—There is no coherent story in the book. It consists of a series of love poems in which a man and a woman speak alternately. A number of songs describe systematically the beauty and excellence of the beloved (called by a modern Arabic term *wasf*, "description"): iv, 1–7; v, 10–16; vi, 4–7; vii, 1–6. There is reference to the bride's seeking for her beloved: i, 7 ff.; iii, 1–5; v, 6–8. There is a description of a festive procession: iii, 6–11. And there are dialogues between the two partners: *e.g.*, i, 9–ii, 7, etc.

Author.—The Hebrew title of the book mentions King Solomon as its author, but several considerations make this improbable: Solomon is referred to in the third person; the language of the book seems to reflect a much later epoch (*e.g.*, there are Persian and perhaps even Greek loanwords); and the city of Tirzah is referred to (vi, 4) in such a context as to make it probable that it is the capital of the northern kingdom of Israel (9th century B.C.). This, alongside the fact that the language contains some archaic elements, seems to suggest that an older text has been revised at a later epoch. The author of the book remains unknown.

Interpretation.—The Song of Solomon has been interpreted in many different ways of which four, described below, are important.

Allegorical.—The allegorical interpretation takes the book as an allegory of God's love for Israel or of Christ's love for the church. This type is represented by the Jewish Targum (the free Aramaic rendering given in the synagogue when Hebrew was no longer understood), which makes it refer to the lawgiving on Mt. Sinai, the history of Israel and the coming of the Messiah. In the Christian Church this interpretation is maintained by the early Fathers, by the Eastern Churches and by many modern Roman Catholic scholars. In medieval mysticism the Song of Songs was applied to the love between Christ and the human soul, and Bernard of Clairvaux gave a famous exposition of it to that effect. The earliest traces of an allegorical interpretation seem to be Rev. iii, 20 (which may reflect S. of Sol. v, 2) and II Esd. v, 23–26 (1st century A.D.).

Dramatic.—The dramatic interpretation is based on the fact that a considerable part of the book is clearly in dialogue form. According to this view, the heroine of the book is a peasant maiden in Solomon's harem, who longs for her shepherd lover and utters her feelings to the ladies of the court; they lead her on to describe her lover and to tell how she came to be carried off by Solomon. Finally her constancy secures her release, and the curtain falls on the sentiment of true affection in viii, 6, 7. This theory is attractive in certain respects, but in view of the absence of drama in the Semitic literatures it is not very probable. Moreover, any progress of action from first to last is difficult to prove. Most advocates of the theory find it necessary to rearrange the sequence of the sections considerably in order to get a coherent story, which seriously weakens their case.

Literal.—The so-called literal interpretation considers the book to be a collection of secular love songs without any religious implications. This theory was introduced in modern research by J. G. Wetzstein, who during the 19th century was Prussian consul at Damascus and whose observations of the wedding customs of Syrian peasants led him to believe that the biblical book is substantially a collection of songs originally sung at such festivities. During the first seven days after the wedding the man and his young wife play the part of king and queen. A threshing board is erected on the threshing floor as a throne, and after the royal couple have taken their seats a dance in their honour begins. The accompanying song to a great extent consists of *wasf, i.e.*, a description of the physical perfections and the ornaments of both. Wetzstein's contribution, which was originally published in the *Zeitschrift für Ethnologie* in 1873, was reprinted by F. J. Delitzsch in an appendix to his *Commentary*, and his theory was accepted by K. Budde (1898) and by many other scholars.

The songs edited by Wetzstein, and folk songs from Palestine later published, indeed show a striking similarity in language and imagery with the Song of Songs—*e.g.*, apart from the *wasf*, the description of the bride as a garden (iv, 12; vi, 2, 3) and many other details. This theory would also account for the reference to Solomon in the Song of Songs: it would be another way of saying that the bridegroom is playing the role of a king. However, the very fact that the young couple in Syria are celebrated as king and queen calls for an explanation.

Another difficulty arises from the fact that almost throughout the Song of Solomon it is the bride and not the bridegroom who takes the initiative, which would be inconceivable in an ordinary Syrian or Palestinian wedding. This has given rise to a fourth theory.

Cultic-Mythological.—The cultic-mythological interpretation is based on the fact that the poems of the Song of Songs are strongly reminiscent of the songs connected with the Sumerian rite of the sacred marriage. This ceremony, an element of the fertility cult of ancient Mesopotamia, most frequently implies the consummation of a ritual marriage between the king and a goddess, represented perhaps by a temple prostitute or priestess, the king playing the role of the fertility god Tammuz. Description songs (*wasf*), the goddess's search for the god and several other typical motifs and expressions occur here for the first time in history, much earlier than the Song of Songs and the modern Arabic folk songs.

The cultic interpretation was inaugurated by Erbt in 1906 and further elaborated by a number of scholars. It implies that rites similar to the Sumerian ones were practised in ancient Canaan—this is to some extent substantiated by the Ras Shamra texts, dating from the 14th century B.C.—and that these practices were in some way or other taken over by Israel. It is known at least that this was the case during the reign of King Manasseh (II Kings xxi). But it is difficult to explain how a collection of more or less pagan cult songs was introduced into the Hebrew canon of Holy Scriptures. One suggested explanation assumes that these songs were used for centuries in popular celebrations in springtime until their original meaning was forgotten, and then were adopted because of the allegorical interpretation which was given to them partly because their performance happened to coincide with the celebration of the Exodus at Passover.

This theory has the advantage over all the others: it accounts for the dialogue form; it is "literal" in that it understands the text as it is without looking for hidden implications; and it even provides a certain basis for an allegorical interpretation, if it may be assumed that the sacred marriage forms the background of the prophetic description of the relationship between Yahweh and Israel as a marriage (Jer. ii, 2; Isa. liv, 4 ff.; lxii, 4 ff.).

The cultic interpretation is accepted by an increasing number of writers, especially since the discovery and publication of many new parallels in Sumerian texts. The main reason for rejecting it is the difficulty of explaining the book's presence in the canon on these premises. The only alternative is the interpretation as secular love songs, the similarity with Sumerian cult poems being accounted for by the assumption that they are dependent on a common tradition of love songs. Some Egyptian collections of love songs, which also offer some parallels to the Song of Solomon, seem to be of a more secular character, although many of them are thought to have originated in the cult of the love goddess Hathor.

BIBLIOGRAPHY.—A good survey of the different interpretations is given by H. H. Rowley in his collection of essays *The Servant of the Lord* (1952). For commentaries, *see* T. J. Meek in *The Interpreter's Bible* (1956); H. Ringgren in *Das Alte Testament deutsch* (1958). For folk songs, *see* St. H. Stephan, *Modern Palestinian Parallels to the Song of Songs* (1923; also in *Journal of the Palestine-Oriental Society*, vol. ii, 1923); S. Linder and H. Ringgren, *Palästinische Volksgesänge*, 1–2 (1952–55). (H. Ri.)

SOLOMON ISLANDS, a chain of islands in the Melanesian area of the southwestern Pacific, which extends in a northwest-southeast direction for almost 900 mi. between latitudes 5° and 11° S., and longitudes 154° 40′ and 162° 30′ E. The group includes the Santa Cruz Islands, about 300 mi. to the east of the southernmost Solomons, and the Lord Howe (Ontong Java) Islands.

The northernmost islands, Buka and Bougainville, are administered by Australia as part of the trust territory of New Guinea (*q.v.*); the remaining islands—including Guadalcanal, San Cristóbal, Malaita, Santa Isabel, Choiseul, New Georgia, Santa Cruz, Lord Howe, Reef and Duff groups and Mitre Island—form a British protectorate. The area of the Australian-administered islands is about 4,100 sq.mi. and that of the British protectorate about 11,500 sq.mi.

The group contains a number of low coral atolls, but the larger islands are all volcanic and rugged. Heights of more than 8,000 ft. are reached on Bougainville and Guadalcanal. Geologically the islands form a continuation of the volcanic arc to the east of New Ireland.

Bougainville (*q.v.*) is the largest of the group. South of Bougainville the islands are arranged in two parallel chains, the western including Vella Lavella, Kolombangara, New Georgia and Guadalcanal, and the eastern, Choiseul Island, Santa Isabel Island and Malaita. The two chains converge on the southernmost island, San Cristóbal.

The climate is equatorial, with constant heat, high humidity and no dry season. Rainfall on most of the islands exceeds 100 in. a year. The vegetation is a heavy forest and, as in most island groups, the animal life is restricted.

The islands were discovered in 1568 by the Spaniard Alvaro de Mendaña, who tried to establish a colony in 1595. The expedition, which failed miserably, is the subject of a novel by Robert Graves (see *Bibliography*). Only toward the end of the 18th century was European knowledge of the group completed, by the voyages (1766–92) of Philip Carteret, Count Louis Antoine de Bougainville, John Shortland, Antoine Raymond Joseph de Bruni d'Entrecasteaux and others. The British protectorate was established over the southern islands in 1893, after a century of European contact with generally unfortunate results.

A German protectorate over the northern Solomons was declared about 1885, but in 1899 all except Buka and Bougainville were transferred to Great Britain in return for recognition of German claims in western Samoa. The German islands were occupied by Australian troops in 1914, and after 1920 the two northern islands were administered by Australia. In 1942 the Japanese advance

into the Pacific swept the Solomons where its further progress was checked. The fighting in the following three years was among the bitterest in the Pacific, particularly the long struggle on Guadalcanal (*see* WORLD WAR II: *The War in the Pacific*).

The total population of the Solomons is about 154,000, of whom 124,076 (1959 census) live in the British protectorate. The most populous island is Malaita, with (1957 est.) 47,000 inhabitants. The larger islands are almost entirely populated by Melanesians, but there has been much racial admixture and there is a great variety of physical types and linguistic groups. Ten separate languages are spoken on Bougainville. A few Polynesians are found on the atolls.

There are only two towns, Kieta on the east coast of Bougainville, and Honiara, administrative capital of the protectorate, on the north coast of Guadalcanal.

In 1960 a new constitution was brought into operation for the protectorate. The legislative council, presided over by the high commissioner for the western Pacific, has an official majority. The executive council is divided equally between official and unofficial members.

Primary education is mostly provided at subsidized mission schools, and there are a secondary boarding school and a training college for teachers and carpenters. There is a central hospital at Honiara, besides a leprosarium at Tetere, and district, rural and mission hospitals.

Copra is the mainstay of the economy of the Solomons, and is produced by both native growers and European estates, the latter mainly on Guadalcanal, the Russell Islands, San Cristóbal Island and Santa Isabel Island. Great damage was done to the coconut plantations during World War II, and even by 1960 only about two-thirds of the prewar area of 64,000 ac. were productive. No new estate plantings of coconuts had taken place, although there had been a small increase in native copra production from Santa Isabel Island and Malaita. There had, however, been a marked improvement in the quality of copra produced, following the granting of a premium for the better grades by the copra board, which is the sole purchaser of copra in the islands.

The administration had endeavoured to introduce cacao as an alternative cash crop; it was taken up by some native growers on Malaita, and a little is produced by Europeans in the western Solomons.

Only two other commercial activities have more than a local importance: the Kieta area of Bougainville produces a little gold, and the islands of Guadalcanal and Vanikoro support a lumbering industry that makes a small contribution to the export trade. About four-fifths of the exports by value, however, are accounted for by copra.

See PACIFIC ISLANDS; *see* also references under "Solomon Islands" in the Index.

SOLOMON'S-SEAL, a perennial herb of the genus *Polygonatum,* of the lily family (Liliaceae). There are about 30 species native to north temperate regions. The plant springs from a fleshy, creeping rootstock on which the scars of the previous year's shoots leave curious seallike marks—hence the common name.

Two species occur in eastern North America and three are found in Great Britain.

The single erect or arching stem, one to eight feet high, bears ovate or lance-shaped, sharp-pointed, sessile leaves in the axils of which appear narrow greenish, whitish or pinkish bell-shaped flowers, on slender, drooping stalks, followed by globular, pulpy, usually bluish berries.

In the United States various species of *Smilacina,* a closely allied genus, are called false Solomon's-seal.

SOLOMOS, DIONYSIOS, COUNT (1798–1857), was the first poet of modern Greece to show the capabilities of its spoken language (the *dimotiki*) when inspired by wide culture and a first-rate lyrical fancy. Born in Zante, he was educated in Italy (1808–18), at Venice, Cremona and Padua, after which he returned to Zante. His earliest poems were written in Italian but in 1822 he finally determined to write in the spoken tongue of Greece. His noble *Hymn to Liberty,* in 158 four-line stanzas, was composed in May 1823, and his poem on the death of Lord Byron in 1824–25. The unfinished *Lambros,* a romantic poem of the revolutionary times written in ottava rima (*q.v.*), was begun in 1826. To this period (1823–28) belong also some shorter lyrical pieces and some satires, of which the most notable is *I Gynaika tis Zakynthos* ("The Woman of Zante"), a long sketch written mostly in poetical prose. In 1828 he migrated to Corfu, where he remained until his death. His lyrical exuberance was curbed by a growing preoccupation with German theories of dramatic form and by an inhibiting dissatisfaction with the as yet meagre resources of his chosen linguistic medium. These impediments, together with a disastrous family quarrel (1833–38), explain why his major poems of this period remain fragmentary. Nonetheless, *O Kritikos* ("The Cretan," 1833), the second and third sketches of *Oi Eleftheroi Poliorkimenoi* ("The Free Besieged") of Missolonghi (before and after 1844), and *O Porphyras* ("The Shark," 1849) exhibit, even in their fragments, a sense of rhythm, a "curious felicity" and a melody of cadence not found in his *juvenilia.*

Jenkins, *Dionysius Solomós* (1940); P. Michalopoulos, *Dionysios Solomos* (in Greek) (1931); M. Sigouros, *O Solomos* (in Greek) (1958). (R. J. H. J.)

SOLON (active about the beginning of the 6th century B.C.), an Athenian statesman and the earliest Greek lawmaker about whose achievements anything is known in detail. He was born about 640, son of Execestides, a nobleman or eupatrid (*see* EUPATRIDAE).

Political Background.—Solon grew up in a period of bitter political strife, the symptoms of which were the attempt of Cylon, supported by his father-in-law, Theagenes, tyrant of Megara, to become tyrant of Athens (in 636 or 632), its savage suppression by the Alcmaeonid Megacles, involving (so his opponents averred) an act of gross impiety, the breach in the eupatrids' monopoly of knowledge of the law by the publication of Draco's code *c.* 621 and the vengeance, backed by Delphi, taken on the Alcmaeonids and their followers for impiety, probably toward the end of the century (*see* ALCMAEONIDAE). This political strife arose from the interplay of two factors, rivalry among a number of powerful aristocratic families and economic stress among the common people. Under this stress many had fallen into debt-slavery and many had lost effective ownership of their ancestral plots of land. There seem to have been some aristocrats, among them Solon, who were prepared to make concessions to the oppressed lower class partly by attacking the more or less complete monopoly exercised by the eupatrids over the control of the state, partly by attempting to relieve the economic burdens of the poor. Draco's publication of the law was a step in the former direction. A bolder step toward solving both sides of the problem was taken when Solon was appointed archon with legislative powers in 594/593 and was given the special task of reconciling the contending factions. This role of standing as a kind of umpire between two extreme parties rests on the unimpeachable evidence of Solon's own poems, as does the fact that, like all moderate reformers, he was criticized by both right and left, by the right more severely. The detail of his reforms, for which *see* below, rests on less secure evidence.

Solon's Participation in Athenian Foreign Policy.—Solon seems to have played a part in external affairs also during this period. His name is connected with two of the three main enterprises which engaged Athenian arms at this time. In a prolonged struggle with her neighbour, Megara, the Athenians wrested from her the possession of the island of Salamis off the coast of Attica. According to Plutarch in his *Life of Solon* it was the esteem Solon won in this war that led to his appointment as archon and, if that is right, the campaign must be dated *c.* 600–595. Later, according to some accounts, Salamis was lost again and was recovered by Pisistratus, acting with the support of Solon, *c.* 565. Some historians, both ancient and modern, have held that only this second war, under the generalship of Pisistratus, actually occurred. Solon

himself refers in his poems to the war for Salamis, but says nothing to fix the date decisively.

At some time in the 590s Thessaly, Sicyon and Athens combined successfully against Cirrha, in what was known as the First Sacred War, for the control of Delphi and its oracle. Solon was said to have advocated Athenian participation in this enterprise, but the general in command was Alcmaeon.

It is fairly certain that Athens engaged in a war for Sigeum in the Troad at the end of the 7th century. Solon's name is not connected with this war. Nevertheless it is highly probable that the war was to some extent concerned with trade through the Hellespont and this would fit with the view that Solon saw an extension of foreign trade as a partial solution to Athens' economic difficulties.

Absence from Athens.—Tradition said that after his year of reform Solon voluntarily absented himself from Athens for a long period of travel, partly for its own sake, partly for trade. He is supposed to have visited Egypt, the court of Croesus in Lydia, and Cyprus, where he stayed with the prince Philocyprus and gave his name to the city called Soli. The poems contain a hint of a visit to Egypt and a specific mention of a visit to Soli in Cyprus, though neither reference gives any clue as to the date of the visit. The visit to Croesus (*q.v.*), though the most famous, and vouched for and described in detail by Herodotus, must be rejected as mythical on chronological grounds.

Tyranny of Pisistratus.—The last recorded chapter in Solon's life was his impassioned resistance to the setting up of Pisistratus as tyrant of Athens *c.* 561. Dramatic colour was added to the story by the alleged facts that the mothers of the two men were related and that Pisistratus had once been Solon's lover. The poems voice some sharp warnings against the dangers of tyranny, but there is no certainty that these fragments are to be dated to the end of Solon's life. He cannot have survived long after the setting up of the tyranny, if indeed he lived so long.

The story of Solon's life was much obscured in antiquity by his inclusion in the list of the Seven Sages with their many apocryphal encounters.

Evidence of Reforms.—For the details of Solon's reforms we depend largely on two main sources, Aristotle's *Constitution of Athens* (*q.v.*) and Plutarch's *Life,* and they in turn must have drawn heavily on the writings of the Atthidographers, local historians of Attica who wrote between the end of the 5th and the middle of the 2nd century B.C. Modern scholars have differed widely as to the reliance to be placed on this evidence, one school holding that virtually nothing more was known to these writers than is available to us today and that most of what was attributed to Solon was the result of arguments, often faulty, from survivals, while to others it has seemed probable that these writers had access to much that has now been lost, whether it was oral tradition or, more important, the remains of the original wooden tablets (*axones* or *kurbeis, see* below) on which Solon published his laws, and that it is therefore possible to recover in some detail the shape of his reforms. The latter view has been adopted in the following account, which treats the reforms under two main heads (1) social and economic and (2) constitutional.

Social and Economic Reforms.—Solon's boldest step, and one which he himself puts in the forefront of his reforms, was the so-called "shaking-off of burdens" (*seisachtheia*). Much of the land of Attica was occupied by smallholders who had fallen into debt and had to pay their creditors a sixth part of the yearly produce (hence they were called "sixth parters" or *hectemoroi*). The fact that a man's land was thus encumbered was marked by the setting up of a mortgage pillar (*horos*) upon it. By the harsh law of debt anyone who defaulted on these payments could be enslaved. Solon describes how he freed the earth by plucking up these pillars (canceling, we must suppose, the debts to which they witnessed) and released those who had been enslaved, even buying back those who had been sold abroad. He prohibited enslavement for debt in the future, thus putting Athens in the van of progress in this respect—even at the end of the 5th century there were several Greek states where enslavement for debt still prevailed. He tried to ensure that debtor slaves actually secured their freedom, and that in future children, for example, were not illegally pledged into slavery, by providing that in certain cases anyone who wished (*ho boulomenos*) could proceed judicially against a wrongdoer and not, as heretofore, only the wronged party. To help those who still could not hope to secure a living from the land he encouraged the teaching of crafts, offered citizenship to craftsmen who wished to settle permanently in Attica and banned the export of all produce of the land with the significant exception of olive oil. He was also alleged to have altered the coinage to fit the Euboic-Corinthian instead of the Aeginetan standard so as to facilitate Athenian trade with the west. It is doubtful however whether Athenian coinage goes back as far as Solon and it may be that all he did here was to alter the system of weights and measures from the Aeginetan to the Euboic-Corinthian. In the early days of coinage the effect of this would have been almost equally important. All this suggests that Solon had an idea, however rudimentary, that where a population can no longer be fed on home produce the necessary imports of food can be paid for only by exports. Other laws aimed at strengthening the individual family and the state on the one hand vis-à-vis the powerful clan on the other. Thus he allowed a man who had no male issue to adopt a son and leave his property to him by will; hitherto such property had devolved on the kin in a prescribed order. He made sumptuary restrictions on funerals and instituted or confirmed a state cult of the dead (*genesia*) peculiar to Athens, over against the clan cults. Finally several rules analogous to Roman praedial servitudes are attributed to Solon; to take a single example, a law prescribed the distance various kinds of tree must be planted from the neighbour's boundary.

Constitutional Reforms.—Here Solon's principal step was to break the eupatrid monopoly of the chief magistracies, especially the archonships. To this end he used a classification of the free population by the produce of their land. There were four classes, *pentacosiomedimnoi* whose land produced more than 500 *medimni* of grain (1 *medimnus* = $1\frac{1}{2}$ bushel) or 500 *metretae* of wine or oil (1 *metretes* = $8\frac{1}{2}$ gal.), *hippeis* (horsemen) with more than 300 *medimni, zeugitai* (probably hoplites or infantrymen) with more than 200 and *thetes* (day labourers) all the rest. Anyone who belonged to the highest class (or perhaps to one of the two highest classes) might now become an *archon* (*q.v.*) whether he was an eupatrid or not. Minor offices were open to members of the third class. The *thetes* could hold no office, but they were assured membership of the popular assembly (*ecclesia; q.v.*). This assembly probably gained in power, though less no doubt than the oppressed class would have liked, and less than was later asserted by those who tried to push back all important democratic institutions to Solon. It now played a part in the election of the archons, who had hitherto probably been chosen by the aristocratic council of the Areopagus (*q.v.*). Each of the four tribes of which it was composed chose 10 men and out of these 40 the archons were selected by lot. This was less democratic than would have been the right to elect the archons direct. Solon allowed appeals in certain cases (it is not possible to say precisely which) from the judicial decisions of magistrates to the assembly, called when exercising this function *heliaia*. Aristotle, in his *Constitution of Athens*, followed by Plutarch, tells us that Solon instituted a council (*boule; q.v.*) of 400 whose function would have been to prepare business for the assembly. We can say nothing of the composition or method of election of this council except that it would not have included *thetes* and that it would have been open to noneupatrids. This Solonian council of 400 has been doubted, perhaps without sufficient ground. If accepted, it implies that Solon contemplated fairly regular meetings of the assembly and that he was not prepared either to allow these meetings a completely free rein or to entrust control of them to the Areopagus, which, being composed of former archons, was bound for many years to be dominated by eupatrids. Finally Solon attempted to bring home to each citizen his responsibility for the stability of the state by the ordinance that, when civil strife broke out, no one should remain neutral. Some such constitutional provisions as these would square well with Solon's own claim that he had "stood casting a strong shield round both parties and had allowed neither to triumph unjustly"

and with the stress that he lays in several passages on the need for a reform in the administration of justice.

Solon's laws, not of course neatly docketed into social, economic and constitutional but probably arranged under the heads of the various magistrates to whose spheres of duty they severally related, were published on wooden prisms (*axones* or *kurbeis*) which could be revolved to show their three faces. A substantial proportion of these archaic objects probably survived at least to the end of the 5th century B.C. and remnants of them down to Plutarch's day in the 1st century A.D. There were at least 16 of them since we have a quotation from the 16th. The law of homicide remained substantially as Draco had published it, but Solon made drastic changes in the rest of Draco's code. Thus 4th-century writers and speakers tended to regard the law of Athens as being basically Draco's law of homicide together with the laws of Solon, though they were well aware that in the course of two centuries many amendments and additions had been made to them.

In neither the economic nor the constitutional sphere was Solon wholly successful. Thus, though we hear nothing further of the *hectemoroi*, a discontented class of smallholders and city dwellers remained to form part of the backing for Pisistratus' bid for tyranny. And, although he had made noneupatrids eligible for office, he could not ensure that they actually be elected: struggles over elections to the archonships remained bitter and, after an illegal usurpation by one Damasias in 582–580, a compromise had to be adopted—we do not know for how long it lasted—by which the office was shared roughly equally between eupatrids and noneupatrids.

Solon was also the earliest Athenian poet, using verse in the elegiac, iambic and trochaic metres as a vehicle both for his political and social programs and for his views on morals and religion. His poems express, with a measured passion, respect for the individual and loyalty to the state as reciprocally enhancing aims in the life of the community. A much more skeptical view of the evidence for Solon's reforms is taken by, for example, C. Hignett (*see* bibliography), who also holds that the legislation should not be placed in Solon's archonship but was passed toward the year 570. *See* also references under "Solon" in the Index.

SOLOR and **ALOR ISLANDS,** two closely associated island groups of the Nusa Tenggara Islands, Indonesia, stretching 150 mi. (240 km.) eastward from Flores to Timor. They consist of five large islands, Solor (pop. [1930] 35,000), Adonara (25,000), Lomblen (32,000), Pantar (8,000), and Alor (51,000, the largest), together with a number of smaller ones. The population in the 1960s was not much higher, because of the slow natural growth and emigration.

Alor, divided from Timor by Ombai Strait, 17 mi. (27 km.) wide, is very mountainous (Mt. Kolana 6,033 ft. [1,839 m.] and Mt. Muna 4,724 ft. [1,440 m.], both old volcanoes), and is much broken up by steep ravines, with only one plateau and some small coastal plains. It is largely covered with low trees and alang grass. The coast is mostly rocky, with few indentations, but on the west coast, Kalabahi Bay, 10 mi. (16 km.) long and nearly a mile wide, divides a northwestern promontory from the rest of the island, with which it is connected by a very low alluvial isthmus about 2½ mi. wide. Pantar is high (Mt. Delaki 4,478 ft. [1,365 m.]), with a rugged coast; Lomblen has several active volcanoes, Ili Labalekang (5,394 ft. [1,644 m.]) and Ili Lewotolo (4,757 ft. [1,450 m.]); Adonara has a volcano, Ili Boleng (5,443 ft. [1,659 m.]), and a plateau, ringed with hills, reaching 3,000 ft. (914 m.); Solor is hilly also. The islands have a pronounced seasonal rainfall, October to April being the wet season. All the islands are administratively attached to the districts of the Nusa Tenggara Province (Lesser Sundas).

Racially the people are Oceanic Negroids, short statured with dark brown to black skin and wavy to kinky hair. Many languages are spoken, all belonging to the Malayo-Polynesian family. Apart from the Muslims, who are often immigrants, and some Christian communities along the coasts, the local inhabitants are animists. The Dutch introduced a political hierarchy, giving local rule to the coastal rajas, but these rajas have only nominal control over the interior tribes. Social organization there centres around kinship and village groups. The villages are small, usually on defensive mountain sites, and consist of several communal houses, each occupied by a lineage group. House styles differ, but the rectangular stilt house with high pyramidal roof predominates. The high points of village life are weddings, burial feasts, and housebuilding ceremonies, each one accompanied by much dancing. Each occasion also involves exchange of the local currency, consisting of pigs, gongs, and *mokos* (the highly prized metal kettle drums). The women cultivate the fields, on which dry rice, maize (corn), beans, and various tubers are grown. Pigs and chickens are generally raised, but carabao and horses are few, mostly raised on the western islands, and often owned by the rajas. Lomblen and Adonara export copra, and Lomblen also has a fishing industry.

The Portuguese, who had settlements on the Islands in the 16th century, were dislodged by the Dutch in the 17th and 18th centuries, but the Portuguese claims were not given up until a treaty between the Netherlands and Portugal was ratified in 1859. In 1949 the islands became part of Indonesia.

See C. A. Du Bois, *People of Alor* (1944). (J. O. M. B.)

SOLOTHURN (French SOLEURE), an ancient little town of Switzerland and capital of the canton of Solothurn, lies on both banks of the Aare River, 25 mi. (40 km.) S of Basel and 18 mi. (29 km.) NNE of Bern. Pop. (1960) 18,394, German-speaking, with a small Protestant majority. The chief building is the 18th-century Cathedral of SS. Ursus and Victor, which stands on the site of a far older edifice. Since 1828 it has been the cathedral church of the bishop of Basel. Other notable buildings are the Jesuit Church, the Clock Tower (13th century), and the 15th-century town hall. The early 17th-century arsenal contains the finest collection of armour and old weapons in Switzerland, and the modern museum houses a collection of fossils from the Jura Mountains and a Madonna by Hans Holbein the Younger. There are some fine 16th-century fountains in the town, which in its older parts with the massive bulwarks still keeps much of its medieval aspect. In the modern suburbs and neighbouring villages there is some industrial activity, which includes watchmaking, engineering, and the manufacture of electric motors, electrical and technical equipment, and screws. The position of Solothurn at the foot of the Jura and close to the navigable portion of the Aare has always made it a meeting point of various routes; seven railway lines branch off there. A mile north of the town is the Hermitage of St. Verena, in a striking rock gorge, above which rises the Weissenstein ridge.

A 16th-century rhyme claims for the town the fame of being the oldest place in Celtis save Trier. Certainly its name, Salodurum, is found in Roman inscriptions, and the remains of the Roman castrum still exist. Its position as commanding the approach to the Rhine from the southwest has led to its being more than once strongly fortified. The medieval town grew round the castrum and the house of secular canons, founded in the 10th century in honour of St. Ursus and St. Victor by Queen Bertha, wife of Rudolph II, king of Burgundy. The provost and canons had many rights over the town, but in 1218, having shaken off the jurisdiction of the canons, who were then taken under its protection, Solothurn became a free imperial city. In 1295 it allied itself with Bern, through which it was drawn into association with the Swiss Confederation. An attempt to surprise it in 1382, made by the Habsburgs, was foiled, and resulted in Solothurn's sharing in the Sempach War. It was included in the Sempach ordinance of 1393 and in the great treaty of 1394 by which the Habsburgs renounced their claims to all territories within the Confederation. In 1411 Solothurn sought in vain to be admitted into the Confederation, a privilege only granted to it in 1481 at the diet of Stans.

In the 15th century also, by purchase or conquest, the town acquired the main part of the territories forming the present canton. In 1529 the majority of the communes went over to the reformed faith and assisted Huldreich Zwingli at the Battle of Kappel (1531), but in 1533 the old faith regained its sway, and in 1586 Solothurn was a member of the Golden, or Borromean, League. Solothurn was the residence of the French ambassador from 1530 to 1792. From the 16th century it had an aristocratic form of government, but this was finally broken down in 1831, and in 1832 Solothurn joined the League to guarantee the maintenance of the new cantonal constitutions. Though distinctly a Roman Catholic centre, it did not join the Sonderbund, and it voted in favour of the federal constitutions of 1848 and 1874. (*See* also SWITZERLAND: *History*.)

SOLOTHURN CANTON has an area of 305.5 sq.mi. (791 sq.km.), of which about 97% of the land is productive. Pop. (1960) 200,816, almost entirely German-speaking, with three-fifths Roman Catholics and two-fifths Protestants. The canton has an irregular shape because it consists of territories acquired at different dates by its capital town, from which it took its name. It includes the foothills of the Jura Mountains (*q.v.*) and consists of a plain along the Aare Valley projecting into Bern Canton, with the Bucheggberg in the southwest between the Aare and Emme (a right-bank tributary which joins the Aare near the town of Solothurn). Farther downstream, a part of the Aare Valley belongs to Bern, but Solothurn resumes possession farther on, and there the Aare receives the Wigger on the right bank at Aarburg and the Dünnern from the Jura on the left bank at Olten. The Hasenmatt (4,751 ft.; 1,448 m.) is the highest point of the Weissenstein section of the Jura, across which the canton stretches in a broad belt to the north where, at various points, it shares with Bern the Birs River, a tributary which joins the Rhine near Basel. Beyond the Birs are two separated districts that belong to the canton: Leimental, including the well-known pilgrimage centre Mariastein, and Kleinlützel. The northern part of the canton and its detached fragments touch the canton of Bern and the half cantons of Basel-Stadt and Basel-Land. The districts of the canton form part of the diocese of Basel, with the town of Solothurn as the site of the bishop's palace. Besides Solothurn, the other chief towns are Olten (20,044) and Grenchen (18,000), both on the Aare River.

Until the mid-19th century the cantonal activities were mainly agricultural and pastoral, and although these are still important, the population is largely engaged in the manufacture of a variety of products, particularly around Solothurn, Olten, and Grenchen. The chief manufactures are watches, jewelry, shoes, cotton goods, paper, cellulose, cement, auto parts, iron and steel products, and electrical equipment for communications. The canton has excellent rail and road connections. Olten is a railway junction where the direct lines from St. Gotthard Pass via Lucerne, and from Geneva, Zürich, and Basel all unite.

Solothurn Canton is divided into ten administrative districts with 132 communes. The cantonal constitution dates from 1887, but was substantially revised in 1895. The *Kantonsrat* (legislative assembly, consisting of 144 deputies) is elected on the principle of proportional representation. The *Regierungsrat* (executive) consists of five members. Both groups hold office for four years, but any 4,000 citizens can demand a popular vote on *Abberufung*, or recall, to decide whether the existing members shall continue or not. Also by the obligatory referendum (since 1869 all laws and financial resolutions passed by the *Kantonsrat* must be approved by a popular vote) and by the right of "initiative" 2,000 electors can compel the legislative assembly to consider any legislative proposal. Since 1856, the demand of 3,000 electors has been sufficient to necessitate a popular vote as to the advisability of any change in the constitution. The representatives to the federal *Ständerat* (Council of States) and to the federal *Nationalrat* (National Council) are also chosen by popular vote. (E. A. BH.)

SOLOVETS ISLANDS (SOLOVETSKIYE OSTROVA), a group of islands of the U.S.S.R. located in the White Sea off the end of the Onega Peninsula (Onezhskiy Poluostrov). Administratively they are part of Archangel Oblast'. The islands are formed of morainic deposits and cover 134 sq.mi. (347 sq.km.). The largest, Solovetskiy Island, has an area of 100 sq.mi. (259 sq.km.). On it is located the former monastery, founded in 1436, which was one of the largest, richest, and most famous in north Russia. Its wealth derived largely from salt working. After the reform of the Orthodox Church, Old Believers of the monastery underwent a siege from 1667 to 1676. (R. A. F.)

SOLOVIEV, SERGEI MIKHAILOVICH (1820–1879), author of the first comprehensive, scholarly account of Russian history, whose historiographic approach influenced later scholars, was born on May 5 (old style; 17, new style), 1820, in Moscow. After studying at the university there, he traveled abroad, returning to become professor of Russian history (1847–79). In his monumental *Istoria Rossii s drevneishikh vremën* ("History of Russia from Ancient Times" [to 1774]; 29 vol., 1851–79; 15 vol., 1959–65), influenced by Hegelian thought, he viewed Russian society as having undergone a process of organic evolution, developing from the primitive clan (*rod*) to the patriarchal state, and finally to enlightened absolutism. By stressing environmental factors, he set the achievements of individual rulers in historical perspective. Russia, he maintained, was inherently part of Europe, despite the cultural backwardness which it was the function of the state power, assisted by the "best" elements of society, to overcome. His mild liberalism was combined with Great-Russian patriotism and loyalty to the Orthodox Church, and he supported Alexander II's expansionist Balkan policy as well as his domestic reforms. He died in Moscow on Oct. 4 (O.S.; 16, N.S.), 1879.

See K. D. Grothusen, *Die Historische Rechtsschule Russlands* (1962). (J. L. H. K.)

SOLOVIEV, VLADIMIR SERGEEVICH (1853–1900), Russian philosopher and theologian whose work foreshadowed the 20th-century movement for the reconciliation of the Christian churches with one another and with scientific thought. He was born in Moscow on Jan. 28 (new style; 16, old style), 1853, the second son of the historian S. M. Soloviev (*q.v.*). Soon outgrowing the fashionable materialism that he had adopted as a child, he studied science, philosophy, and theology before graduating as doctor of philosophy at Moscow University. His thesis, *The Crisis of Western Philosophy—Against the Positivists* (1874), won him a teaching post; but the liberal character of his Christianity soon brought him into conflict with the reactionary forces in the university, and in May 1875 he was encouraged to go abroad for 15 months. After visiting London, Cairo, and Paris, he returned to Moscow, but was suspended from teaching again in 1877 and then transferred to the Ministry of Public Instruction in St. Petersburg. An appointment at the University of St. Petersburg (1880) was terminated after he had appealed for clemency toward the murderers of the emperor Alexander II (1881). Thereafter he lived as an independent writer. He died at Uzkoye, near Moscow, on Aug. 13 (N.S.; July 31, O.S.), 1900.

Soloviev was a man of vast and conscientious learning, familiar with patristic and gnostic literature on the one hand and with modern philosophy on the other. Among his most significant writings are *Philosophical Principles of Integral Knowledge* (1877); *Lectures on Godmanhood* (1878–81; Eng. trans. 1944); *Critique of Abstract Principles* (1880); three discourses *In Memory of Dostoevski* (1881–83); *Russia and the Universal Church* (in French, 1889; Russ. trans. 1913; Eng. trans. 1948); *The Meaning of Love* (1892–94; Eng. trans. 1946); *The Justification of the Good* (two editions, 1897 and 1898; Eng. trans. 1915); and *Three Conversations on War, Progress, and the End of Universal History* (1899; Eng. trans. 1915). He also published poems, influential on the Russian Symbolists. "Godmanhood" (*Bogochelovechestvo*) meant the raising of the individual man to identification with Christ, the historically incarnate God, by means of "free theurgy" (the cooperation of workers, artists, and mystics), "free theocracy" (the Christian organization of society), and "free theosophy" (the integration of religion, philosophy, and science). Opposed to the intolerant and exclusively "Russian" religion of the Slavophils (*q.v.*), Soloviev strongly advocated an understanding between the Russian Orthodox Church and Roman Catholicism and blamed the Byzantines for their part in the original schism between East and West. Nationalism he deplored as generative

of hatred among mankind, but he had a patriotic belief in Russia's destiny in a Christian world. The second collected edition of his works, in ten volumes, appeared in 1911–14.

SOLSTICE, in astronomy either of the two points at which the sun reaches its greatest declination north or south (Lat. *solstitium,* from *sol,* "sun," and *sistere,* "to stand still"). Each solstice is upon the ecliptic (the projection of the plane of the earth's orbit on the celestial sphere) midway between the equinoxes, and therefore 90° from each. The term is also applied to the time at which the sun reaches the point thus defined (about June 21 and Dec. 21). Compare EQUINOX.

SOLUNTUM (Greek SOLOEIS or SOLOUS; Phoenician KFRA; modern Italian SOLUNTO), an ancient town on the north coast of Sicily, 10 mi. (16 km.) E of Palermo and about 2 mi. NE of Bagheria. Lying on the southeast side of Mt. Catalfano (1,227 ft.), in a naturally strong position 600 ft. (180 m.) above sea level, it commands a fine view. Soluntum was one of the three chief Phoenician towns in the island and remained a Carthaginian possession until the First Punic War, when after the fall of Panormus (Palermo; 254 B.C.) it went over to the Romans. Excavations brought to light considerable remains of the Hellenistic and Roman periods; the older town was probably nearby.

SOLUTIONS are homogeneous mixtures of two or more substances in relative amounts that can be varied continuously up to what is called the limit of solubility. Solutions in water of common salt, sugar, alcohol, and carbon dioxide gas are familiar examples. The history of chemistry is witness to the extraordinary importance of solubility. The apparently mysterious nature of solution and recrystallization invited the speculations of ancient philosophers. Medieval alchemists were almost as interested in finding a universal solvent (alkahest) as they were in gold and in eternal life. Modern chemists take advantage of differences in solubility to separate and purify materials, and for methods of chemical analysis. Materials for laboratory vessels and chemical manufacturing equipment are selected to resist the solvent action of their contents; many liquids are valuable chiefly as solvents. Most chemical reactions occur in solution and are influenced by the solubilities of the reagents.

Life processes depend largely on solutions. Oxygen from the lungs goes into solution in the blood plasma, unites chemically with the hemoglobin in the red blood cells, and is released to the body tissues (*see* BLOOD). Products of digestion also are carried in solution to the different parts of the body (*see* DIGESTION). The dependence of life on the freedom of complex molecules in solution to move and rearrange is strikingly shown by the cessation of metabolic processes on freezing. Nitrogen is soluble in water, blood, and fatty tissues. At sea level, the body of a man of average weight contains about one litre (1.15 g.) of dissolved nitrogen. Living at an altitude of 6,000 ft. (where air pressure is about 0.8 atmosphere) he has 0.8 as much (0.92 g.). The pressure of the air breathed by a deep-sea diver increases by one atmosphere for about every 34 ft. of depth; thus at 100 ft. below the surface the amount of nitrogen dissolved in his body builds up toward roughly 4×1.15 g. As he ascends this extra nitrogen leaves solution and may form bubbles that produce intense pain, block circulation in his blood vessels, and even result in his death. Sometimes called the bends, this condition may be relieved if the victim is put into a pressure chamber and compressed until the bubbles disappear. The pressure is then reduced only as fast as the excess nitrogen can escape through his lungs. Helium is less soluble than nitrogen in body fluids; and helium-oxygen mixtures sometimes are used in place of compressed air in especially deep dives (*see* DIVING APPARATUS; CAISSON DISEASE).

Common salt (sodium chloride) can be dissolved to a limit of approximately 26 weight percent (*i.e.,* about 26 g. of salt per 100 g. of solution); at this concentration the solution is saturated since any added salt remains undissolved. The solubility of common salt increases only slightly with temperature. Sugar dissolves in water up to concentrations of 64.2% at the ice point (0° C; 32° F), 69.2% at body temperature (37° C; 98.6° F), and 82.3% at the boiling point (100° C; 212° F). Alcohol and water mix in all proportions. Carbon dioxide CO_2 gas at one atmosphere pressure dissolves in water up to a limit of 0.145% at 25° C (77° F)—less as temperature increases, more at higher pressures. In a bottle of carbonated water (*see* SOFT DRINKS) at a pressure of two atmospheres, twice as much could be dissolved. It is convenient to remember that one litre of CO_2 dissolves in one litre of water under one atmosphere pressure at 20° C (68° F). Carbon dioxide is 13 times as soluble in benzene as it is in water. The gases of the air all are soluble in water; fishes extract the dissolved oxygen through their gills.

A solid substance dissolved in a liquid is easily detected as a residue by evaporating the solvent. Its presence may also be detected if, when part of the liquid is removed by evaporation or freezing, any property such as density, colour, refractive index, vapour pressure, or freezing temperature changes.

Although the term solution usually suggests a liquid solvent, it applies equally to mixtures of gases. Air is basically a solution of nitrogen, oxygen, argon, water, carbon dioxide, and minute amounts of hydrogen, neon, krypton, xenon, and helium (*see* AIR). Liquid air has a blue colour from its oxygen. If allowed to boil away, the nitrogen escapes more rapidly than the oxygen; the blue colour gradually deepens, and the boiling point gradually rises (*see* OXYGEN: *Preparation*).

There are also solid solutions. For example, ordinary alum $KAl(SO_4)_2 \cdot 12H_2O$ (colourless), and $KCr(SO_4)_2 \cdot 12H_2O$ chrome alum (violet) have crystals so nearly alike in form that they crystallize together from water solution. The crystals vary in colour depending on the relative concentrations of the two alums in the solution (*see* ALUM).

The adjective soluble broadly indicates that a substance goes into solution (whether or not the process involves a chemical change). The colour of iodine (*q.v.*) dissolved in carbon tetrachloride is practically identical with that of iodine vapour (*i.e.,* violet); evidently the iodine molecules are scarcely altered by contact with those of the solvent. However, a solution of iodine in ether is brown, indicating the formation of a chemical complex. The iodine can be recovered by letting the ether evaporate. But when copper dissolves in a dilute solution of nitric acid in water, nitric oxide NO gas is evolved, the copper loses electrons and forms the blue, hydrated copper ion: probably $Cu(H_2O)_4^{2+}$. If the liquid is evaporated, a solid, deep-blue salt remains: cupric nitrate $Cu(NO_3)_2 \cdot 6H_2O$.

Solvent and Solute.—For a solution of a solid or a gas in a liquid, the liquid is customarily designated as the solvent, the substance added is called the solute. If both components are liquids, the distinction loses significance; the one present in smaller concentration is likely to be called the solute.

Concentration.—The concentration of any component in a solution may be expressed in units of weight, or volume, or in moles (gram molecules; *see* MOLECULE). These may be mixed; *e.g.,* weight percent, mole fraction, mole percent, moles per litre, moles per kilogram. The last two are usually used for solutions in water.

Electrolytes and Nonelectrolytes.—Crystals of some salts contain lattices of ions; *i.e.,* atoms or groups with alternating positive and negative charges (*see* ELECTRICITY: *Ions*). To dissolve such a crystal the attractions of the oppositely charged ions (largely responsible for cohesion in the crystal) must be overcome by electric charges in the solvent. These may be furnished by the ions of a fused salt, or by electric dipoles in the molecules of the solvent, as indicated by a high dielectric constant (*see* DIPOLE MOMENTS). Such solvents include water, methyl alcohol, dioxane, liquid ammonia, and hydrogen fluoride. The ions of the solute, surrounded by dipolar molecules of solvent, are detached from each other and free to migrate to charged electrodes. Such a solution can conduct electricity, and the solute is called an electrolyte (*see* ELECTROCHEMISTRY).

The potential energy of attraction between simple, nonpolar molecules (nonelectrolytes) is of very short range; it decreases

approximately as the 7th power of the distance between them. According to this, the energy of attraction between a pair of molecules separated by two molecular diameters is only $\frac{1}{64}$ of what it is at one diameter. For electrolytes the energy of attraction and repulsion of charged ions (like charged spheres) drops only as the first power of the distance; thus their solutions have very different properties from those of nonelectrolytes. The best solvents for one are poorest for the other; although solutions of electrolytes conduct electricity, those of nonelectrolytes do not.

Metallic Solutions.—Metals conduct electricity by having free electrons that can wander through the metallic solid or liquid. Many different metals are miscible in the liquid state, sometimes forming recognizable compounds; some are sufficiently alike to form solid solutions (*see* ALLOYS). A few metals dissolve slightly in their own molten salts. Mercury dissolves at 25° C without chemical change in liquid active phosphorus P_4 to a concentration of 0.03%.

Theories.—The earliest general theory of solutions was based on the concept of osmosis (*q.v.*). If a solution is separated from the pure solvent by a membrane that is permeable to the solvent but not to the solute, the solution will tend to become more dilute by absorbing solvent through the membrane. This can be stopped by establishing on the solution a specific excess of pressure (called the osmotic pressure). J. H. van't Hoff (1886) showed that if the solute is so dilute that its partial vapour pressure above the solution obeys Henry's Law (*i.e.*, is proportional to its concentration in the solution) then osmotic pressure varies with concentration and temperature approximately as it would if the solute were a gas occupying the same volume. This relation led to equations for determining molecular weights of solutes in dilute solutions through effects on the freezing point, boiling point, or vapour pressure of the solvent.

Van't Hoff specified that the gas law as applied to osmotic pressure has limited application; some of his contemporaries assumed that it held also in concentrated solutions. But, for example, when it was used in an attempt to distinguish solvent water from water of hydration in a concentrated solution of calcium chloride, the alleged water of hydration so calculated exceeded all the water in the solution. It became evident that the difference of water pressure in balance on two sides of a semipermeable membrane depends not only on the concentration of solute molecules but also on their attraction for water molecules.

The modern theory of nonpolar solutions is based on the statistical behaviour of a mixture of molecules in chaotic thermal disorder. If the attractions among molecules of like and unlike species are all the same, then the escaping tendency of any species depends simply on its fraction in the mixture (Raoult's Law). If they are unlike and there is a valid theory of how the attraction between the unlike species depends on the attractions in the pure liquids then (if the distribution is still in a state of maximum chaos) there is a basis for calculating the relative amounts of the three sorts of attraction in the mixture. This affords a foundation for a theory of solution applicable for all fractions of the components.

There is abundant evidence that pure liquids and mixtures of nonpolar, reasonably symmetrical molecules are kept by thermal motions in a state of maximum disorder, altogether different from the long-range order existing in crystals. For example, phosphorus, composed of rotating, tetrahedral molecules P_4, melts at 44.1° C, but the liquid can be kept at room temperature (about 20° C) for long periods, and droplets in vacuo have been cooled to −70° C. If the liquid contained any trace of crystallike structures, it surely could not remain liquid under such enormous supercooling.

SOLUTIONS OF NONELECTROLYTES

The properties of nonionic solutions are best described in terms of departures from those of a hypothetical model in which the intermolecular forces of attraction and repulsion are all the same. Such a model is called an ideal solution. There is no change in total volume or temperature when it is formed by mixing its pure liquid components. The escaping tendency of individual molecules is the same in pure liquid and in solution, and the vapour pressure of one species therefore simply depends upon the ratio of the molecules of that species to the total number in the solution. If the solution is composed of n_1 molecules of species 1 and n_2 of species 2, the respective mole fractions of the two species are $x_1 = n_1/(n_1 + n_2)$ and $x_2 = n_2/(n_1 + n_2)$ and $x_1 + x_2 = 1$. If the vapour pressures of the two pure components are p_1^0 and p_2^0, their partial vapour pressures over the solution are $p_1 = p_1^0 x_1$ and $p_2 = p_2^0 x_2$. Total vapour pressure is $p = p_1 + p_2 = p_1^0 x_1 + p_2^0 x_2$ (*see* VAPORIZATION).

This relation was discovered in 1886 by François Marie Raoult (*q.v.*). Its simple, statistical significance was apparently not appreciated, and it was not until much later that it was recognized as an appropriate ideal solution law. That function was temporarily ascribed to van't Hoff's Law, according to which the osmotic pressure of a dissolved substance is equal to the pressure it would exert if in the form of a gas in the same volume. Raoult's Law is obeyed by many mixtures with only moderate deviations throughout the range of composition. It is possible, furthermore, to predict which components are likely to show fair agreement with it. The van't Hoff Law, on the other hand, holds reasonably well only at high dilution, because it takes no account of the specific character of the solvent; this is treated simply as supplying volume for a quasi-gas solute.

Chemical Interactions.—There are several sources of departure from ideality. One is an excess attraction between unlike molecules, such as would be expected in a mixture of phenol C_6H_5OH (weakly acidic) with aniline $C_6H_5NH_2$ (weakly basic). This reduces what otherwise would be the escaping tendency of each component, and the vapour pressures are less than ideal. It occurs also in mixtures of chloroform $CHCl_3$, (weakly acidic) with acetone $(CH_3)_2CO$ (weakly basic), as illustrated in fig. 1. The dotted lines correspond to Raoult's Law; this interaction is to be regarded as specific, selective, and hence chemical. Note that in spite of the interaction the vapour pressure of each component approaches the ideal line as the mole fraction of the other approaches zero.

The terms acid and base are used in the way proposed by G. N. Lewis, a base being a substance with electrons that fit into vacant orbitals of an acid. Bases and acids are in this sense electron donors and electron acceptors (*see* ACIDS AND BASES). Basic character is closely related to low ionization potential. Typical bases include pyridine, amines, acetone, ether, and aliphatic sulfides and iodides. Base strength of aromatics increases in this order: benzene, toluene, *p*-xylene, *o*-xylene, *m*-xylene, mesitylene, naphthalene, phenanthrene. Typical acids are $SnCl_4$, SO_2, BCl_3, and BF_3. The halogens are acids with strengths that increase as follows: Cl_2, Br_2, I_2, IBr, BrCl, and ICl.

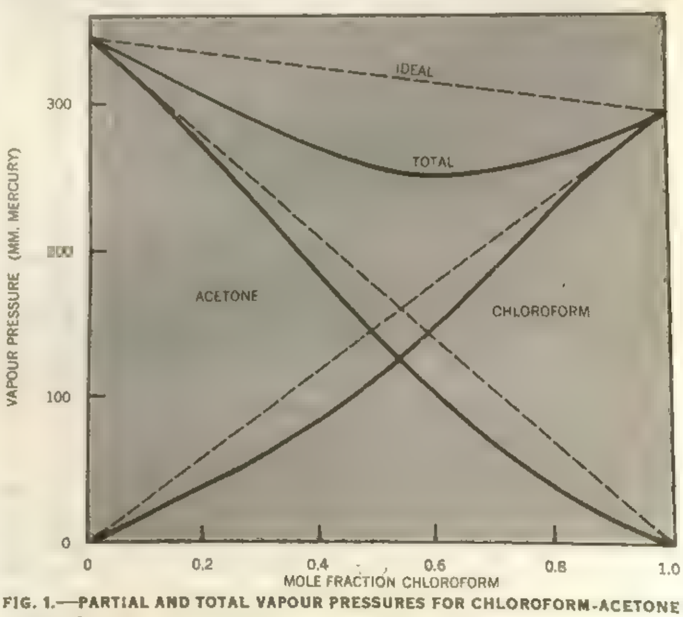

FIG. 1.—PARTIAL AND TOTAL VAPOUR PRESSURES FOR CHLOROFORM-ACETONE AT 35.17° C

Association.—In a mixture of a polar component (its molecules contain electric dipoles) with a nonpolar species, the nonpolar species tends to be squeezed out of the mixture, resulting in vapour pressures in excess of ideal (especially if the polar species is associated through hydrogen bonds, as are water, liquid ammonia, liquid hydrogen fluoride, the alcohols, and the carboxylic acids).

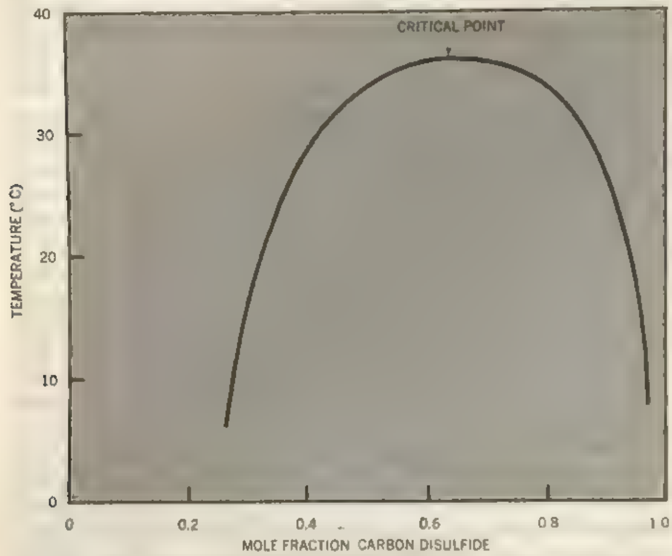

FIG. 2.—SOLUBILITY OF CARBON DISULFIDE WITH METHYL ALCOHOL

This effect often proceeds to the extent of forming another liquid phase, as is the case with mixtures of water with such nonpolar liquids as the hydrocarbons, carbon tetrachloride, and carbon disulfide. Methyl alcohol, CH_3OH, less strongly hydrogen-bonded than water, forms two liquid layers at room temperatures with nonpolar carbon disulfide CS_2. Their mutual solubility increases with temperature by reason of increasing molecular motion until the two phases coalesce at the critical temperature 36.5° C as shown in fig. 2.

Regular Solutions.—A third factor contributing to departure from ideality is inequality in forces of a general, nonselective nature (London forces), such as are responsible for the attractions between the symmetrical, monatomic molecules of the rare gases. They arise from mutual perturbations of the rapidly moving electrons in molecules that are close to each other. The theory of this kind of interaction was developed by F. London (1930) on the basis of quantum mechanics. The attractive potential between a pair of molecules depends on the number and what may be called looseness of their electrons, as indicated by optical polarizability and zero-point energy or, alternatively, low ionization potential (*see* PHYSICS: GENERAL SURVEY: *Atomic and Nuclear Structure*). The potential is of very short range, is additive (*i.e.*, not saturating or selective), and it is not affected by temperature.

According to London's analysis, energy of attraction ϵ_{12} between two unlike molecules is approximately the geometric mean of the potential between the like species ϵ_{11} and ϵ_{22} (*i.e.*, $\epsilon_{12} = \sqrt{\epsilon_{11}\epsilon_{22}}$). This is less than the arithmetic mean of ϵ_{11} and ϵ_{22}; therefore, when two liquids with different intermolecular attractions are mixed, expansion and absorption of heat result, and vapour pressures rise higher than Raoult's Law predicts.

Assuming that thermal agitation suffices to mix molecules with maximum randomness, J. H. Hildebrand and S. E. Wood integrated all the pair potentials in a mole of liquid to give the energy of vaporization, and derived a formula for deviation from Raoult's Law in terms of the energy of vaporization:

$$RT \ln (f_2/f_2^0 x_2) = V_2\phi_1^2(\delta_2 - \delta_1)^2 \qquad (1)$$

Here R is the constant of the ideal gas laws: 1.985 calories per mole per degree absolute temperature T; f_2^0 is the escaping tendency (or fugacity) of pure liquid component *2* and is p_2^0 corrected for the nonideal gas behaviour of the vapour; f_2 is p_2 similarly corrected. V_2 is the volume per mole of component *2*; ϕ_1 is the volume fraction of component 1. The δ values, designated by Hildebrand and R. L. Scott as solubility parameters, are theoretically the square roots of the respective energies of vaporization per mole of the pure liquid components. Practically, the parameters are better determined directly from solubility data. Deviations from Raoult's Law increase mainly with the square of the difference between the solubility parameters of the components. Values for representative liquids are given as Table I.

TABLE I.—*Solubility Parameters δ and Molal Volumes V at 25° C*

Liquid	Formula	V(cc/mole)	δ(cal/cc.mole)^{½}
Perfluoroheptane	C_7F_{16}	225	6.0
2,2,4-Trimethyl pentane	i-C_8H_{18}	166	6.9
n-Heptane	C_7H_{16}	147	7.4
Silicon tetrachloride	$SiCl_4$	115	7.6
Cyclohexane	c-C_6H_{12}	109	8.2
Carbon tetrachloride	CCl_4	97	8.6
Chloroform	$CHCl_3$	81	9.0
Benzene	C_6H_6	89	9.2
Carbon disulfide	CS_2	60	10.0
Bromoform	$CHBr_3$	88	10.5
Bromine	Br_2	52	11.5
Phosphorus (liquid)	P_4	70	14.4

With increasing unlikeness, as measured by $(\delta_2 - \delta_1)^2$, the deviations from ideality increase, as illustrated in fig. 3. The ordinate is the ratio $f_2/f_2^0 = a_2$, the activity; in its pure liquid $a_2 = 1$. Two nonpolar, nonreacting substances with equal parameters can be expected to give an approximately ideal solution, with activities corresponding to line A. Moderate differences in solubility parameters but equal molal volumes give activities of type B. Greater differences yield curve C, indicating a critical point. Still greater differences give curves of type D, with two compositions (at the ends of the horizontal line) with the same activity. This corresponds to two liquid layers. Equation (1) shows that the lower the temperature the greater the deviation from ideal for the same value of the difference $(\delta_2 - \delta_1)^2$. These curves all approach the ideal line A at the upper end, but deviate increasingly toward the lower end. When only a small proportion of component *2* is present, a molecule of component 1 is surrounded mainly by those of the same species, and hence its escaping tendency is not greatly altered. It is altered most at the low end, where the molecules of one kind tend to be surrounded by those of the other.

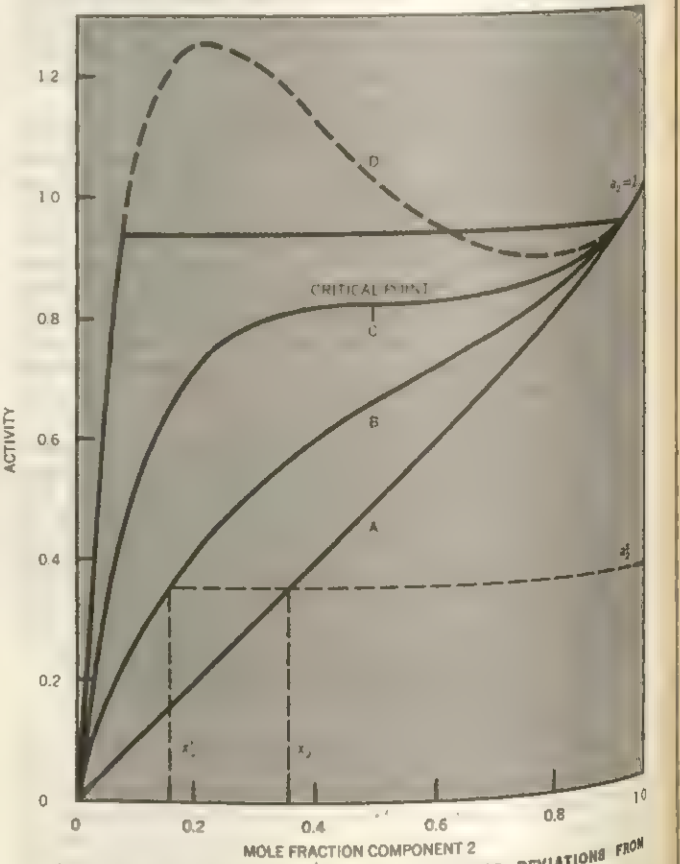

FIG. 3.—ACTIVITY *v.* MOLE FRACTION FOR VARYING DEVIATIONS FROM RAOULT'S LAW (*see* TEXT)

Liquid-Liquid Solubility.—The unlikeness that opposes complete mutual miscibility of liquids in the case of carbon disulfide and methanol (fig. 2) consists largely of hydrogen bonding; *i.e.*, of methanol molecules with each other. Fig. 4 shows curves for the solubility of perfluoroheptane C_7F_{16} which has a very low solubility parameter (6.0) with five other liquids. From Table I it may be seen that the critical temperatures required for complete mixing rise in order of increasing unlikeness as measured by the difference between solubility parameters.

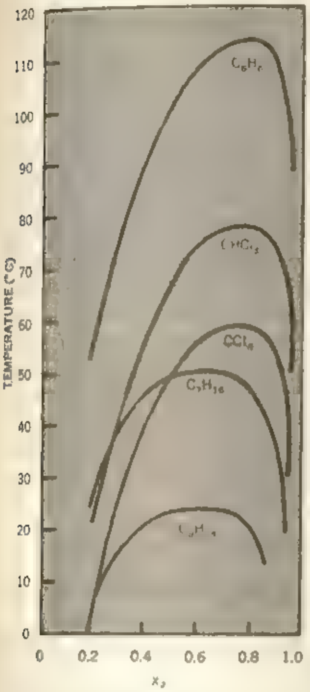

FIG. 4.—SOLUBILITY OF PERFLUOROHEPTANE C_7F_{16} WITH OTHER LIQUIDS

Solubility of Solids.—The fugacity of a crystalline solid is lower than that of its supercooled liquid, since the solid is the stable form below the melting point. The activity ratio f_2^s/f_2^0 is less than 1, and depends on the molal heat of fusion ΔH^F and the distance below the melting point T_m as given by

$$\log_{10}\frac{f_2^s}{f_2^0} = \frac{-\Delta H^F}{2.3R}\,\frac{T_m - T}{T_m T} \quad (2)$$

If the solid dissolves to form an ideal solution, then $f_2^s/f_2^0 = x_2$; and x_2 can be calculated by aid of this equation. It is the value of x_2 in fig. 3 where a_2^s cuts line A.

In a solvent in which the deviation from ideality corresponds to curve B, the solubility would be x_2'; *i.e.*, where the activity along curve B reaches a_2^s. It would be still less if the system followed curve C, and so on. In a solvent with which the solute combines chemically (as in a system like that shown in fig. 1) the solubility would be greater than the value predicted by $\delta_2 - \delta_1$, possibly even greater than ideal.

The way in which the solubility of a solid varies with solvent and temperature is illustrated in fig. 5 for solutions of iodine. Plots of log x_2 against log T have the advantage of giving virtually straight lines except near the melting point. The solid lines represent solutions in which there is practically no chemical interaction, as indicated by their violet colour, identical with that of iodine vapour. The dotted lines represent solutions of different colours: red in benzene, brown in ether, yellow in water, and so on. In the violet solutions only London forces are acting; in the other cases, the specific chemical interaction alters their positions and slopes. The lines for the violet group present a regularity not exhibited by the others. They were designated by Hildebrand as regular solutions, characterized by maximum randomness in the mixing of the molecules, one of the assumptions made in deriving equation (1). This equation accounts reasonably well for the positions in this family of lines, despite the enormous range in solubility.

The other solutions present a more complex problem, involving selective chemical interactions, reducing the randomness, enhancing the solubility over what it would be if the solution were regular, and diminishing the rate of increase of solubility with temperature. The colours of the complexes not only differ from that of iodine in the visible spectrum, but (as discovered by H. A. Benesi and Hildebrand, 1947) show strong absorption bands in the ultraviolet region.

Iodine has a high solubility parameter (14.1) and its solubility falls off rapidly with decrease in the parameters of violet solvents, as illustrated by the following data. These give the solubility of iodine at 25° C in mole percent ($100x_2$) in solvents of widely different solubility parameters δ_1. (Because the parameter for iodine is higher than those for the solvents, the order is the reverse of that in fig. 4.)

	Ideal	CS_2	$CHCl_3$	CCl_4	$SiCl_4$	C_7F_{16}
$100x_2$	25.8	5.46	2.28	1.15	0.50	0.019
δ_1	14.1	10.0	9.0	8.6	7.6	6.0

Solubilities calculated through equation (1) agree reasonably well with these experimental values. Solubilities in the solvents that give nonviolet solutions are higher than they would be in the absence of complexing. Ether $(C_2H_5)_2O$ (solubility parameter 7.5), for example, would in the absence of complexing be only about as good a solvent as heptane C_7H_{16} (*see* fig. 5).

The effect of difference in melting point on the solubility of otherwise similar solid substances is illustrated by the isomers of dinitrobenzene. Their solubilities in benzene are given in Table II together with their melting points and densities. These three

TABLE II.—*Melting Points, Densities, and Solubilities of Dinitrobenzenes in Benzene at 25° C*

Dinitrobenzene isomer	Melting point, °C	Density	Solubility, mole fraction
meta	37 6	1.575	0.376
ortho	116 0	1.590	0 175
para	170 0	1 625	0.031

isomers, when dissolved in benzene, lower its vapour pressure equally. The lowering is less than ideal, because of the polar nature of the two nitro groups, but the effect is practically the same for each isomer; it is the number of nitro groups (not their positions or the overall dipole moment) that is responsible.

The different solubilities of the solid forms of the dinitrobenzenes depend almost entirely on the different crystal-lattice energies. The molecules of the para form are most symmetrical, pack most tightly in their crystal, and are least soluble (*see* SOLID STATE PHYSICS).

Gas Solubility in Liquids.—The solubility of a gas that can be liquefied under pressure can be treated by the method used for the vapour pressure of liquid mixtures. Liquid chlorine, for example, has a vapour pressure of 3.66 atmospheres at 0° C. Its ideal

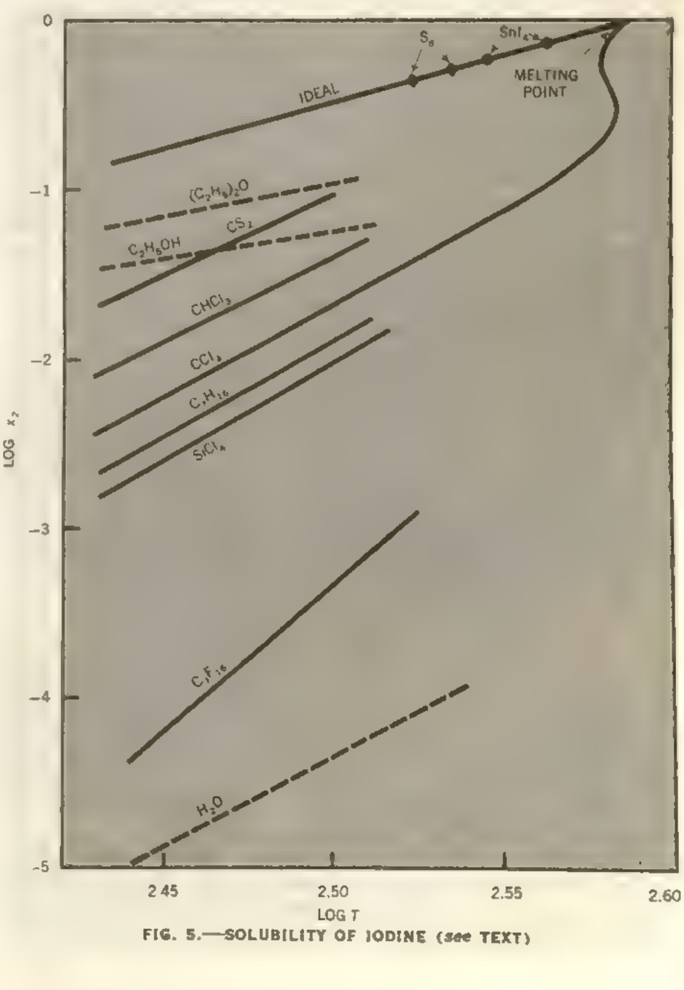

FIG. 5.—SOLUBILITY OF IODINE (*see* TEXT)

solubility at 1 atmosphere and 0° C is therefore $x_2 = 1/3.66 = 0.273$. Its measured solubility in carbon tetrachloride is nearly the same (0.298). The agreement is even closer if the vapour pressure is corrected to fugacity, which gives $f_2/f_2^0 = 0.286$. Its solubility in perfluoroheptane, which has a solubility parameter much smaller than that of chlorine, is considerably less than ideal (0.164).

The higher the pressure required to condense a gas (*i.e.*, the lower its boiling point) the lower its solubility (in the absence of chemical interaction). Also, the low-boiling gases, with their low attractive forces, dissolve to a greater extent as the solubility parameter of the solvent decreases. These relations are illustrated in Table III.

TABLE III.—*Solubility of Gases*

Solvent	δ	Solubility ($10^4 x_2$) at 1 atm. and 25° C					
Gas		He	H_2	N_2	O_2	Ar	Kr
n-C_7F_{16}	6.0	—	14.0	38.7	55.3	—	—
n-C_7H_{16}	7.5	2.5	6.9	—	—	25.0	67.6
c-C_6H_{12}	8.2	—	—	7.6	—	14.9	46.7
CCl_4	8.6	—	3.2	6.4	12.0	13.4	—
C_6H_6	9.2	0.78	2.6	4.5	8.2	8.8	27.3
CS_2	10.2	—	1.6	2.2	4.4	4.9	—
H_2O	—	0.07	0.14	0.12	0.23	0.25	0.45
Boiling point ° K		4.2°	20°	77°	90°	87°	121°

These gases have difficulty in penetrating the strong hydrogen bonds in water. But ammonia, which is moderately hydrogen-bonding and also strongly basic, dissolves readily in ethyl alcohol, and still more easily in water. The figures for x_2 at 1 atmosphere and 0° C are typical: toluene 0.26, ether 0.79, ideal 23.8, ethyl alcohol 39.8, water 48.1.

Molecular Weights of Solutes.—For the more quantitative aspects of solution theory the point of departure remains the ideal solution. Allowance for deviations from ideality can be made fairly well; also, the activity of the solvent approaches ideality as the mole fraction of the solute approaches zero.

For example, molecular weights of substances in dilute solutions (even if they are not ideal) can be determined by measuring the effect of moderate amounts of solute on the activity of the solvent (*see* MOLECULE). The more nearly the solution conforms to Raoult's Law the more precise the result; it is advantageous, therefore, to choose an efficient solvent, or at least to extrapolate a series of measurements to zero mole fraction of solute. The solute will lower the vapour pressure of the solvent, increase its boiling point (nonvolatile solute), depress its freezing point (pure crystals of solvent), and affect the osmotic pressure (*i.e.*, the hydrostatic pressure that must be applied to the solution to keep it in balance with pure solvent from which it is separated by a membrane to which the solvent, but not the solute, is permeable).

Vapour Pressure.—Let a solution be composed of N_1 moles of solvent and N_2 moles of solute. If molal weight is M, and direct weight is w, Raoult's Law may be written $(p_1^0 - p_1)/p_1 = N_2/N_1 = w_2M_1/M_2w_1$. Taking known w_2, w_1 and M_1, and measuring the drop in vapour pressure produced by a nonvolatile solute, M_2 (the molal weight of the solute) can be calculated.

Boiling Point.—The drop in vapour pressure that would be produced by adding solute at constant temperature can be offset by raising the temperature enough to restore the pressure. The following simple mathematical identities can be written.

$$\left(\frac{\partial x_2}{\partial T}\right)_p = -\left(\frac{\partial x_1}{\partial T}\right)_p = \left(\frac{\partial x_1}{\partial p_1}\right)_T \left(\frac{\partial p_1}{\partial T}\right)_{x_1}$$

For an ideal solution $(\partial x_1/\partial p_1)_T = 1/p_1^0$ and in general $(\partial p/\partial T)_v = p\Delta H^{vap}/RT^2$. Since there is no heat of mixing $\Delta H^{vap} = \Delta H_1^{vap}$, and at the boiling point $(\partial x_2/\partial T)_p = \Delta H_1^{vap}/RT_b^2$. For small values of solute mole fraction x_2, write $x_2 = \Delta T_b \Delta H_1^{vap}/RT_b^2$, from which the molal weight M_2 of the solute can be calculated from the measured rise ΔT_b in boiling point.

Freezing Point.—Equation (2) for ideal solubility may be used to find the molal weight of a solute from the effect of a known weight of solute in depressing the freezing point of a known amount of solvent (mole fraction x_1); thus

$$-\ln x_1 = \frac{\Delta H_1^F}{R}\frac{T_m - T}{T_m T} = \ln(1 - x_2) = x_2 + \frac{x_2^2}{2} + \frac{x_2^3}{3} + \dots$$

When the solute mole fraction is small, higher powers may be neglected; $T_m - T = \Delta T$ the freezing-point depression, and $T_mT \cong T_m^2$; therefore $x_2 = \Delta H_1^F \Delta T/RT_m^2$. By determining x_2 from a measurement of ΔT for solute weight w_2 in N_1 moles of solvent, the molal weight M_2 of the solute can be calculated. To obtain precise values of N_2 a series of points for x_2 against ΔT should be taken and extrapolated to $w_2 = 0$.

Osmotic Pressure.—A mole of solvent can be transferred to a solution in either of two reversible ways. If the solvent is transferred by distillation the change in free energy F is $\Delta F = -RT \ln (f_1/f_1^0)$. If it is forced out at pressure P through a semipermeable membrane $\Delta F = P\bar{V}_1$. V_1 is the partial molal volume of the solvent, V_1 its molal volume. The two are virtually identical when the solute is dilute, or when the solution is ideal. Equating these $P\bar{V}_1 = -RT \ln (f_1/f_1^0)$; if the solution is ideal $f_1/f_1^0 = N_1/(N_1 + N_2)$ and $\bar{V}_1 = V_1$, the latter because there is no volume change on mixing the components of an ideal solution. Therefore

$$PV_1 = RT \ln \frac{N_1 + N_2}{N_1} = RT \ln \left(1 + \frac{N_2}{N_1}\right)$$

Now

$$\ln\left(1 + \frac{N_2}{N_1}\right) = \frac{N_2}{N_1}\left[1 - \frac{1}{2}\frac{N_2}{N_1} + \frac{1}{3}\left(\frac{N_2}{N_1}\right)^2 - \cdots\right]$$

When N_2/N_1 is small the higher powers can be neglected, and $PV_2 \cong \dfrac{N_2}{N_1} RT$ or $PV = RT$, where V is the volume of solvent containing 1 mole of solute.

The identity in form of the equations for osmotic pressure and ideal gas pressure led to the unwarranted assumption that osmotic pressure is produced through bombardment of the membrane by solute molecules. However, this would assume that any other two energetically equivalent processes must take place by the same mechanism. Osmotic pressure is simply the hydrostatic pressure required to offset the reduction in escaping tendency of the solvent when solute is added.

Experimental measurement of osmotic pressure with most solutions is very difficult, because a suitable semipermeable membrane is usually difficult, if not impossible, to find. However, it is practical for determining molecular weights of high polymers (*see* POLYMERIZATION), for which membranes are easily devised. With these solutes, high concentrations by weight represent very small mole fractions, and exert but minute effects on the vapour pressure or freezing point of a solvent. For example, a solvent vapour pressure of 100 mm. of mercury would be reduced only to 99.9 mm. by 0.001 mole fraction of a solute. The osmotic pressure of the same solution, if the molal volume of the solvent is 100 cc., would be an easily measured 186 mm.

The Gibbs-Duhem Relation.—There are two energetically equivalent ways to remove one component from a mixture containing N_1 and N_2 moles of the respective components. One way is to distill out, say, dN_1 moles of component 1. The other is to remove solution containing dN_1 moles of component 1 with $(N_2/N_1)dN_2$ moles of component 2, and then distill the latter back into the solution. Equating the partial molal free energies $\bar{F}_1$ and $\bar{F}_2$ of these two steps gives $N_1d\bar{F}_1 + N_2d\bar{F}_2 = 0$. This may also be written in the following especially useful way.

$$\left(\frac{\partial \ln f_1}{\partial \ln x_1}\right)_T = \left(\frac{\partial \ln f_2}{\partial \ln x_2}\right)_T$$

Or activities a may be substituted for fugacities f since $a_1 = f_1/f_1^0$, and so on.

This relation was derived by J. W. Gibbs, and later independently by P. Duhem. For a long time it was called the Duhem equation, but is now commonly called the Gibbs-Duhem relation.

There are important corollaries of the Gibbs-Duhem relation. If Raoult's Law holds for component 1 throughout the entire range from $x_2 = 1$ to $x_2 = 0$, then $f_1/f_1^0 = x_1$, $\ln f_1 = \ln f_1^0 + \ln x_1$, and

$\delta \ln f_1/\delta \ln x_1 = 1$; by the Gibbs-Duhem equation $\delta \ln f_2/\delta \ln x_2 = 1$. Integrating gives $\ln f_2 = \ln x_2 + \ln k_2$, where k_2 is a constant of integration. Since component 1 is assumed to conform to Raoult's Law also when $x_2 = 1$ and $f_2 = f_2^0$, therefore, $\ln k_2 = \ln f_2^0$ and $\ln f_2 = \ln x_2 + \ln f_2^0$; *i.e.*, component 2 also obeys Raoult's Law.

If, however, component 1 approximates Raoult's Law only as x_1 approaches 1 (as is usually the case) then k_2 cannot be evaluated, and $f_2 = k_2 f_2^0$ only can be written as x_2 approaches 1. This is known as Henry's Law. It is especially useful for solutions of the low-boiling gases, with solubilities at 1 atmosphere and ordinary temperature that are mole fractions of the order of 10^{-3} to 10^{-4}.

Fig. 1 and 3 show that a component approaches Raoult's Law at the end where it is the major constituent and approaches Henry's Law (*i.e.*, linearity, but of undetermined slope) at the end where it is the dilute. Van't Hoff had to assume Henry's Law for the solute to derive his equation for the osmotic pressure of the solvent; with modern thermodynamics all such equations as those used for determining molecular weights may be derived by starting with Henry's Law and the Gibbs-Duhem relation.

London Forces.—For the attractive potential ϵ_{12} between a pair of nonpolar molecules of different species London derived the equation

$$\epsilon_{12} = -\frac{3}{2}\frac{\alpha_1\alpha_2}{r^6}\cdot\frac{I_1I_2}{I_1+I_2}$$

For like molecules, this reduces to

$$\epsilon = -\frac{3}{4}\frac{\alpha^2 I}{r^6}$$

where α is the polarizability calculable from refractive index, I is ionization potential, and r is distance between molecular centres. The molecules were assumed to be spherically symmetrical and simple in electronic structure.

Most of the substances in actual solutions are much more complex than this simple model represents. They are seldom nearly spherical and their centres of attraction are in the electron clouds around peripheral atoms. They also may have very different repulsive potentials from the r^{-12} usually assumed for mathematical simplicity. In view of these departures from the simple model it is remarkable that a solubility relationship such as equation (1), based on the simple London equation, is as successful as it is for dealing with solutions of divergent components. If the components are similar in type (*e.g.*, a pair of tetrahalides or a pair of paraffins) the neglected factors have a greater tendency to cancel each other than if different types are mixed (*e.g.*, a tetrahalide with a hydrocarbon). Attempts to allow for such differences become so complicated as to be practically inapplicable.

(J. H. HD.)

SOLUTIONS OF ELECTROLYTES

Recognition of electrolytes as a distinct class of substances is best dated from 1800, when Alessandro Volta published the details of the first electric battery (*q.v.*). This new source of appreciable continuous current was shortly exploited by W. Nicholson and A. Carlisle to demonstrate the composition of water by electrolysis. Sir Humphry Davy (1807) prepared sodium and potassium (hitherto unknown elements) by electrolysis of their molten hydroxides. Michael Faraday introduced the terms still in use: electrolysis, electrolyte (for substances that are decomposed by the current), electrode, anode, and cathode. His quantitative studies led to these fundamental observations:

(a) The chemical change occurs only at the electrodes, not in the bulk of the liquid.

(b) The quantity of chemical change (*e.g.*, the mass of each new substance produced) is proportional to the product of the current intensity and the time for which it flows; *i.e.*, to the quantity of electricity passing.

(c) The mass of each new substance formed by a fixed quantity of electricity is proportional to its equivalent weight (*see* EQUIVALENT). In honour of Faraday's contribution, the quantity of electricity that liberates 1 gram equivalent of new substance at an electrode is known as a faraday (96,500 coulombs); underlying (b) and (c) above is the modern understanding that one faraday is Avogadro's number (6.02×10^{23}) of electrons.

Ions.—Faraday also introduced the term ion for the particles that he saw must exist to carry the current through the liquid; the anion being a negatively charged particle, and the cation being a positively charged particle. Ions are responsible for the special properties of electrolyte solutions. It was long believed that ions were generated by the passage of current, but the modern view that they are always present was established (against strong opposition) by S. A. Arrhenius (*c.* 1890).

This conclusion was based largely on the colligative properties of dilute electrolytes (*i.e.*, those based on the number, rather than type, of solute particles present), including freezing-point depression, osmotic pressure, boiling-point elevation, and vapour-pressure depression. While one-tenth of a gram molecule of any typical nonelectrolyte such as sucrose, glycerol, or urea dissolved in one kilogram of water lowers the freezing point by about 0.186° C, the same amount of a typical electrolyte such as sodium chloride NaCl produces nearly twice as great a drop (0.347° C).

In the limit of very low concentrations, when the ions can act nearly independently of one another, the colligative effect of NaCl (two ions: Na^+ and Cl^-) is twice that of a nonelectrolyte; that of $CaCl_2$ (three ions: Ca^{2+} and 2 Cl^-) is three times; that of $Al(NO_3)_3$ (four ions, Al^{3+} and 3 NO_3^-) is four times. With solutions of salts in water the origin of the ions is clear, for the solid salt itself has an ionic structure. The role of the solvent in this case is to surround the ions by layers of water molecules which (because of their polar nature) greatly reduce the intensity of the electric field near the ions; the normal thermal agitation of the molecules of the liquid is then sufficient to prevent the ions from coming together to reform the crystal unless there are relatively high concentrations of ions. All efficient solvents for electrolytes (*e.g.*, water, formamide $O = CH - NH_2$, hydrogen cyanide HCN) have highly polar molecules, which result in a high dielectric constant (permittivity) for the liquid. Molten salts are also substantially ionic in character; high temperature alone frees the ions from their fixed positions in the crystal lattice, producing the typical electrolytic properties of electrical conduction, with chemical change at the electrodes.

Other electrolyte solutions are formed from solutes that are not appreciably ionic in the pure state; most acids fall in this category. Hydrogen chloride gas consists of covalently bound HCl molecules; it can be liquefied by pressure or cooling, and the liquid is virtually a nonconductor. Its solution in water (hydrochloric acid) is a typical electrolyte, having an unusually high conductivity. The solution is almost entirely ionic; thus, for instance, the vapour pressure of HCl gas above a 5% solution in water is barely detectable, since the vapour is in equilibrium with only the minute concentration of molecular HCl in the solution. Acetic acid, an almost entirely nonionic liquid at ordinary temperatures, also dissolves freely in water; in this case most of the solute remains in molecular form and only a small fraction (about 0.5% in a solution containing one mole of acid per litre) exists in the form of hydrogen ions and acetate ions. This can be shown from its relatively low electrical conductivity and from the freezing-point depression of the solution. Most organic acids and bases resemble acetic acid in being so-called weak electrolytes (*i.e.*, incompletely dissociated to ions in water). In less efficient electrolytic solvents, with lower dielectric constants than water, dissociation is reduced, and even salts may exist largely as so-called ion pairs (*i.e.*, pairs [or higher aggregates] of oppositely charged ions bound together).

The laws of chemical equilibrium require that at extreme dilution any electrolyte must completely separate into its ions; in practice the dilution required for typical so-called weak electrolytes is so great that the electrolyte is undetectable. For example, acetic acid at a concentration of 3×10^{-5} moles per litre remains only about half ionized. This concentration corresponds to only two parts of the acid per million of water.

The solvent is fundamental in determining the behaviour of electrolyte solutions. Salts (typical strong electrolytes) usually have high melting points (ranging higher than 1,000° C). The

theory of ideal solutions as shown by equation (2) accordingly leads to the expectation that the solubility of salts in any solvent at room temperature should be very small. Their solubilities in nonpolar liquids such as benzene and carbon tetrachloride are indeed usually indetectable, but in water and similar highly polar solvents they are often freely soluble. Typical saturation concentrations for metallic chlorides are several moles per kilogram of water. To reconcile this observation with equation (2) consider NaCl as a typical salt. The crystal consists of unhydrated Na^+ and Cl^- ions; equation (2) accordingly gives the mole fraction of unhydrated ions in the solution at saturation. However, most of the ions in the solution have become hydrated through interaction of their strong electric fields with the electric dipoles of water molecules. Thus the mole fraction in terms of the total dissolved electrolyte is large, though the mole fraction of unhydrated ions is very low as required by theory.

The strength of ion interactions with water molecules also is shown by volume changes that occur when electrolytes are dissolved. The volume of a dilute solution of a solid electrolyte in water is nearly always appreciably less than the sum of the separate volumes of electrolyte and water. The apparent molar volume of the solute ϕ_V is computed by subtracting the volume of water from the total volume of solution and dividing the result by the number of moles of solute. This quantity is nearly always less than the volume of a mole of the solid electrolyte; in a number of cases it is actually negative. For example, when caustic soda NaOH is in a very dilute aqueous solution, it is found that $\phi_V = -5.2$ cm.^{3}/mole, compared with a molar volume of 18.8 cm.^{3}/mole for the solid caustic soda. The volume of the solution in this case is less than that of the water alone. These observations are explained in terms of electrostriction, a shrinkage in volume of the water in the vicinity of the ions. The effect increases sharply as the charge on the ions increases and the ionic radius decreases. It is shown very clearly by the volume change on neutralization of dilute solutions of strong acids and bases; *e.g.*,

$$\underset{\text{hydrochloric acid}}{H^+ + Cl^-} + \underset{\text{sodium hydroxide}}{Na^+ + OH^-} \longrightarrow \underset{\text{sodium chloride}}{Na^+ + Cl^-} + \underset{\text{water}}{H_2O}$$

There is a volume increase of 22 cm.^{3} for each mole of acid and base neutralized; this arises from the combination of the charged species H^+ and OH^- to form the neutral molecule H_2O. This reaction has an interesting consequence in the behaviour of water under high pressures. Under ordinary conditions water undergoes a very slight self-dissociation:

$$H_2O \rightleftharpoons H^+ + OH^-$$

the equilibrium concentration of ions being only about one ten-millionth of a mole per litre. The electrical conductivity of pure water is accordingly very low, though still accurately measurable. By subjecting water to the extreme pressures (several hundred thousand atmospheres) developed in explosion shock waves, S. D. Hamann found that it becomes as good a conductor as a quite concentrated salt solution. Evidently the concentration of ions is increased by a factor of about a million as the high pressure forces the volume to decrease. By the laws of chemical equilibrium, then, the self-dissociation equilibrium shifts in the direction favouring a smaller volume; *i.e.*, the extent of dissociation increases. Such effects are of great importance in geochemical studies (*see* GEOCHEMISTRY).

Activity Coefficients.—The terms activity and activity coefficient are used in representing the thermodynamic properties of electrolyte solutions (*see* THERMODYNAMICS). The mean molal activity coefficient γ of an electrolyte is so defined that it becomes unity in infinitely dilute solution, and its value at finite concentrations is related to the chemical potential μ of the electrolyte:

$$\mu = \mu^0 + RT \ln (m\gamma)^2 \quad \text{(for 1:1 electrolytes such as KCl)}$$
$$\mu = \mu^0 + RT \ln 4(m\gamma)^3 \quad \text{(for 1:2 or 2:1 electrolytes such as } Na_2SO_4 \text{ or } MgCl_2)$$

and so on, where m is the molality (gram molecules of solute per kilogram of solvent) and μ^0 is the chemical potential in a standard state. Activity coefficients may be determined by measurements of the electromotive force of suitable reversible electrical cells, or by measurements of such colligative properties as vapour-pressure lowering, freezing-point depression, or osmotic pressure. Most of the data available in the 1960s were derived from reversible cells or from isopiestic (isobaric) vapour-pressure measurements. In the latter method (R. A. Robinson and D. A. Sinclair, 1933) the solution is held in good thermal contact with a reference solution of known vapour pressure, in a vessel kept at constant temperature and evacuated of air. Distillation of water from one solution to another occurs until their vapour pressures are equal; the solutions are then weighed to determine their equilibrium concentrations. Since the solvent activity is known in the reference solution, that in the other solution is the same. From a series of such measurements at different concentrations combined with the Gibbs-Duhem equation the activity of the solute can be calculated.

The behaviour of strong electrolyte solutions attracted the attention of many of the ablest chemists of the 19th century (*e.g.*, Arrhenius, W. H. Nernst, W. Ostwald, and van't Hoff). The conductance and thermodynamic properties of weak electrolytes HA such as acetic acid (*see* HYDROGEN IONS) were satisfactorily accounted for in terms of the ionization equilibrium

$$HA \rightleftharpoons H^+ + A^-$$

with an equilibrium constant

$$K = \frac{[H^+]\,[A^-]}{[HA]}$$

Efforts were made to try to account for the behaviour of solutions of salts and strong acids and bases in the same way, but neither conductance measurements nor equilibrium studies led to satisfactorily constant values of K. This so-called anomaly of strong electrolytes resulted in the gradual development of the idea that strong electrolytes are completely ionized in solution, and that departures from the behaviour to be expected for an ideal solution of the ions arise from the relatively strong electrostatic forces between ions and from their long-range nature. The modern form of the theory of interionic forces in electrolytes was developed by P. Debye and E. Hückel (1923). In outline their approach is to fix attention on one ion in the solution, the central ion. If it is a positive ion it will tend to attract negative ions and to repel positive ions in its vicinity. Any small element of volume near the central ion therefore will have (on a time average) a slight excess of negative charge. Quantitatively, the distribution of this excess charge can be calculated from Poisson's equation of electrostatics combined with Boltzmann's equation, which states that the concentration of ions that have electrostatic energy E is proportional to $e^{-E/kT}$ (where e is the base of natural logarithms, k is Boltzmann's constant, and T is the absolute temperature). It is found that the excess negative charge density ρ around the central positive ion falls off with the distance r according to the law

$$\rho = \frac{Ae^{-\kappa r}}{r}$$

where A is a constant depending on the dielectric constant and the temperature; κ, a parameter depending on these, is proportional to the square root of the ionic strength I of the solution:

$$I = \tfrac{1}{2}c_1z_1^2 + \tfrac{1}{2}c_2z_2^2 + \cdots$$

summed over all species of ions (1, 2, 3 . . .) in the solution, where c_i is the molar concentration of ions of species i in unit volume (1 litre) and z_i is the number of unit charges carried by the ion.

From the now known charge distribution it is possible by standard electrostatic methods to calculate the extent to which the potential energy of the central ion is lowered by electrostatic interaction with its environment. This energy is a component of the chemical potential μ_i of the ion, and takes the form μ_i (electrostatic) $= -(z_i^2e^2N/2\epsilon)\,\kappa/(1 + \kappa a)$ where N is Avogadro's number, e the electronic charge, ϵ the dielectric constant of the solvent, and a is the average diameter of the ions. Assuming that the electrostatic interactions are the only basis for nonideal behaviour, μ_i (electrostatic) can be identified with $RT \ln \gamma_i$, where γ_i is the

activity coefficient of the ion. The activity coefficients of the individual ionic species cannot be measured, but the Debye-Hückel result can be converted to give the mean activity coefficient $\gamma_\pm$ of the electrolyte. The result for an electrolyte with cation 1 and anion 2 is

$$\log \gamma_\pm = -\frac{A|z_1z_2|\sqrt{I}}{1 + Ba\sqrt{I}} \tag{3}$$

Here A and B are constants involving the dielectric constant and the absolute temperature. For aqueous solutions at 25° C the value of A is 0.51 and B has the value 3.3×10^7 when I is expressed in the usual mole per litre concentration units. Since the diameter a of typical ions is a few angstrom units, the term $Ba\sqrt{I}$ in the denominator is of the order of unity at ionic strengths of about one. At very low ionic strengths, however, the term $Ba\sqrt{I}$ becomes small compared to unity, and the result takes the simpler form

$$\log \gamma_\pm = -A|z_1z_2|\sqrt{I} \tag{4}$$

A great deal of extremely precise work (mainly measurements of the electromotive forces of reversible cells and of freezing points of dilute electrolyte solutions) has established the general validity of equation (4) as a limiting law for strong electrolytes in very dilute solutions. Other thermodynamic properties such as heat of dilution and apparent molar volume for strong electrolytes have also been shown to conform at low concentrations to limiting laws demanding linearity in the square root of the ionic strength. These laws can be derived from equation (4) by partial differentiation: with respect to the temperature to give the law for the heat of dilution, and with respect to the pressure to give the limiting law for the apparent molar volume.

The actual behaviour of the activity coefficients of strong electrolytes is more complicated. Conformity with the limiting law is general at extreme dilutions. Equation (3), in which the ion-size term in the denominator is retained, is adequate up to a few hundredths of a mole per litre in many cases, provided that the ionic diameter a is treated as a parameter that can be adjusted to give the best fit between theory and experiment. Beyond this rather low limit of concentration, however, electrolytes may deviate empirically in two ways from the Debye-Hückel behaviour. What may be called a negative deviation is found with many salts in which the product of the ionic charges z_1z_2 is large, and more especially those in which the negative ion is highly charged; *e.g.*, sulfates SO_4^{2-} and ferrocyanides $Fe(CN)_6^{4-}$. These salts have lower activity coefficients than the Debye-Hückel theory predicts; likewise their equivalent conductances are lower than the values given by the Debye-Hückel-Onsager equation (*see* ELECTRICITY, CONDUCTION OF: *Conduction in Liquids*). N. Bjerrum (1926) explained this type of deviation as arising from ion-pairing, the formation of comparatively stable pairs of ions held together by electrostatic forces. The thermodynamic effects of such ion pairs are similar to those found in the presence of undissociated molecules (as in weak electrolytes) and they can be accounted for by superimposing on the Debye-Hückel model a treatment in terms of a chemical association constant. Bjerrum developed a method of calculating this association constant from electrostatic theory; the calculation usually gives at least the right order of magnitude for the association constant.

The other common type of deviation is found with many of the alkali halides, and in very marked form with the salts of divalent metals and univalent anions (such as magnesium chloride). In these cases as concentration increases, the activity coefficient rises above the Debye-Hückel value; frequently this results in a minimum in the curve and a rapid rise beyond the minimum. The activity coefficient often exceeds the value (unity) appropriate to an ideal solution; as an extreme example, in 5.5 molal uranyl perchlorate $UO_2(ClO_4)_2$ the mean activity coefficient is 1,457. Significantly in these cases the electrical conductance shows no abnormality; the usually accepted explanation of such superideal behaviour is that it is a result of ion-solvent interactions. In the Debye-Hückel treatment the solvent appears only as a dielectric medium in which the ions are immersed.

There is a great deal of evidence, however, that many ions (small and highly charged cations particularly) carry a rather firmly attached sheath of water molecules held in place by ion-dipole forces. Thus the mobilities of such ions are much lower than would be expected from their known sizes in crystals and from hydrodynamic arguments; the viscosities of the solutions are often higher than would be expected from similar hydrodynamic arguments, indicating entities larger than the bare ions. The compressibilities of the solutions indicate the presence of a region of already tightly packed water near the ions. Also, the dielectric constants of the solutions (measured by microwave techniques) suggest that a fraction of the water molecules (proportional to the ion concentration) is immobilized and fails to contribute to the dipole rotation that finds expression in the dielectric constant. Though attempts to determine the number of such bound water molecules by various methods do not agree quantitatively, there is general agreement that the order of hydration numbers of the following cations is $Li^+ > Na^+ > K^+$; and $Mg^{2+} > Ca^{2+} > Ba^{2+}$. In a series of salts such as the chlorides, this is also the order of departures from Debye-Hückel behaviour of the activity coefficients. Following early work by Bjerrum (1918), R. A. Robinson and R. H. Stokes (1949) showed that by making the proper allowance for the presence of hydrated ions, the activity coefficients could be reconciled with the Debye-Hückel equation up to concentrations of several moles per litre.

Transport Processes.—While much knowledge of electrolytes has come from the study of equilibrium properties such as activity coefficients, transport properties are of at least equal importance. Transport properties may be defined as those in which matter or energy flows irreversibly from one place to another; in accordance with the second law of thermodynamics, they are accompanied by an increase of entropy if they occur in an isolated system, or by a decrease in Gibbs free energy if they occur in a system held at constant temperature and pressure (*see* THERMOCHEMISTRY). Those of most interest in considering electrolytes are electrical conduction, isothermal diffusion, viscous flow, and thermal diffusion.

Electrolytic Conduction.—Studies of their electrical conductivity have contributed greatly to the understanding of electrolyte solutions, and also find many applications in chemical analysis. When a chemical reaction involves an increase or decrease in the number of ions in a solution or the replacement of one ion by another of different mobility, the conductivity of the solution changes in a well-understood manner. Thus in the neutralization of sodium hydroxide by hydrochloric acid, the highly mobile hydroxide ion is replaced by a chloride ion, with a decrease in conductivity. When the equivalence point is reached, the solution consists of sodium chloride only, and the conductivity reaches a minimum. As more hydrochloric acid is added, the extremely mobile hydrogen ion of the acid can no longer be neutralized, and the conductivity rises rapidly.

Isothermal Diffusion.—If two solutions of the same solute at different concentrations are placed in contact at the same temperature the solute diffuses from the higher to the lower concentration (the solvent in the opposite direction) until the solution is uniform throughout. The rate at which this isothermal diffusion occurs for a given concentration difference is measured by the diffusion coefficient D. Nernst showed that in the limit of extreme dilution the diffusion coefficient of an electrolyte was simply related to the mobilities of the ions; *e.g.*, for sodium chloride

$$D^0 = \frac{2RT}{F^2}\left(\frac{\lambda^0_{Na^+}\lambda^0_{Cl^-}}{\lambda^0_{Na^+} + \lambda^0_{Cl^-}}\right)$$

where R is the universal gas constant, F the faraday, T the absolute temperature, and λ^0 the limiting equivalent conductance. The form of this relation results from the fact that no net flow of current occurs in the process (in contrast to electrical conduction), so that the sodium and chloride ions are constrained to move in the same direction and with equal speeds. For the same reason, the process at finite concentrations is modified by the electrophoretic effect, but not by the relaxation effect (*see* ELECTROPHORESIS; RELAXATION PHENOMENA).

Viscosity.—In viscous flow each layer of the solution is in motion with respect to neighbouring layers. The external force producing this relative motion is opposed by the viscosity (*q.v.*) or internal friction of the liquid. Electrolytes added to water and other solvents produce a small increase of viscosity arising from the electrostatic forces between ions in neighbouring layers. This effect, which is proportional to the square root of the concentration, was evaluated from the Debye-Hückel-Onsager theory by H. Falkenhagen and M. Dole, and results for very dilute solutions are in accord with their predictions. At more usual concentrations this small change is masked by larger effects arising from interactions between the ions and the solvent; these are approximately proportional to the first power of the electrolyte concentration. When the ions are large compared to water molecules, they act as obstructions in the stream lines of the flow; this effect occurs also with neutral solute molecules such as sugars. A. Einstein showed that this effect should obey the equation

$$\eta_{sol}/\eta_{H_2O} = 1 + 5\phi/2$$

where ϕ is the fraction of the volume occupied by the solute particles, and η is the viscosity of the solution or the water. Smaller ions (about the size of water molecules or smaller) sometimes show a similar effect; this can be explained in terms of a permanent solvation sheath of solvent bound to the ion, increasing its effective size. A few ions (notably iodide ion) produce a marked decrease in the viscosity of water. It is believed that the electric field of such ions, though too weak to establish a permanent solvation sheath, is enough to break down the loose bonding between nearby water molecules and their neighbours, resulting in an increased fluidity.

Thermal Diffusion.—Two solutions of the same concentration but at different temperatures will diffuse when placed in contact (with suitable precautions to prevent convective flow due to density differences). After a considerable time a steady state known as a Soret equilibrium is reached in which the solute is more concentrated at either the hot end or the cold end. In electrolyte solutions the approach to this state can be followed by measurements of the conductivity of the liquid at each end, or of the potential difference between suitable electrodes in each solution. The complex theory of this process involves the simultaneous flow of heat and matter, and along with other coupled-flow processes is one of the important points of growth in the modern theory of steady-state thermodynamics.

SOLVAY, ERNEST (1838–1922), Belgian industrial chemist and social reformer, who developed an important process for making alkali, was born at Rebecq on April 16, 1838. The son of a salt refiner, he attended school in Malonne and later worked for his father at Rebecq. Solvay read books on elementary chemistry and physics and in 1860 became an assistant to an uncle who was head of a small gasworks at Schaerbeek.

In 1863 Solvay developed his process for the production of soda ash, which is considered one of the most important 19th-century advances in industrial chemistry. Replacing the old Leblanc "black-ash" process, Solvay's process was widely utilized in many countries. (*See* also Chemical Industry and Alkali Manufacture.) Solvay became wealthy and contributed to various philanthropies and research organizations. In 1894 he established in Brussels the Institut des Sciences Sociales, which became the Institut de Sociologie in 1901. He opposed the amassing of inherited wealth and proposed a system of social accounting which would replace money. His works include *Science versus Religion* (1879) and *Questions of Social Energetics* (1910). He died at Brussels on May 26, 1922.

SOLWAY FIRTH, a shallow inlet of the Irish Sea between England and Scotland. From St. Bees Head in Cumberland to Abbey Head in Kirkcudbrightshire it is 22 mi. (35 km.) across, and from this line it stretches about 35 mi. farther northeast to the estuaries of the Rivers Esk and Eden at its head. West of its constriction between Bowness and Annan, the firth opens like a funnel, with ramified reentrants, notably at Moricambe Bay on the Cumbrian side and at the mouths of the Nith and Ure Water on the Scottish side. Wide stretches of sand are exposed at low tide, and the estuarine parts are choked by shifting sandbanks. The firth derives its name from the *sulwathe* ("muddy ford") across the Esk Estuary. Naturally the inner part or head of the firth is avoided by shipping, but small vessels from Ireland penetrate as far as Silloth, an artificial port established in 1859 to serve Carlisle. An earlier, short-lived attempt had been made to develop Port Carlisle, east of Bowness, with canal connections from Carlisle. Hadrian's Wall, crossing the isthmian portion of north England from the Tyne Estuary to the Solway Firth, ends on the south shore at Bowness by the lowest ford. The tide advances quickly up the estuary and sometimes forms a bore.

SOMA, in Vedic India, the personification of the fermented juice of a plant most probably to be identified with one or more species of *Ephedra* (*q.v.*). In the Rigveda, the entire ninth book is devoted to hymns in praise of Soma, revered as a god with invigorating qualities. The juice was drunk by priests at the sacrifices and its uses go back to Iranian times; it is called *haoma* in the Avesta (*see* Zoroastrianism). Although Soma was no doubt originally equal to Indra and Agni in importance, his place as a divine link or messenger between man and heaven is gradually assumed by Agni. In the post-Vedic classical period Soma is identified with the moon, which wanes when drunk by the gods but is replenished by the sun. *See* also Vedic Religion.

SOMALILAND, FRENCH (Côte française des Somalis), an overseas territory of France on the East African coast where the Red Sea meets the Gulf of Aden, is bounded by Ethiopia to the north, west, and south, and by the Somali Republic to the southeast. Its area is 8,960 sq.mi. (23,206 sq.km.) and its capital Djibouti (*q.v.*).

Physical Features.—The country consists mostly of sand and stone desert, broken in places by salt lakes and lava streams and by lofty, usually sterile mountain ranges (Musa or Moussa Ali, 6,630 ft. [2,020 m.]) which extend from a coastal plain inland to the Ethiopian highlands. The coast line is deeply indented by the Gulf of Tajura (Tadjoura). The drainage is partly eastward to the coast and partly inland to the lakes, but few streams flow above the surface except after rain. French Somaliland is notable, indeed, for its extreme aridity and torrid climate. From May to September Djibouti usually has an average maximum temperature of 40° C (104° F) and a minimum of 23° (73°); the annual rainfall is less than 5 in. (127 mm.). The cool season is from November to April. The vegetation is generally sparse, much of the country being clad with acacia scrub, and supports a similar fauna to that found in the Somali Republic.

Population.—The chief inhabitants are the Somali and Afar (or Danakil) peoples of the southeastern Cushitic or Hamitic family. They share similar physical features, although the Somali are usually taller than the Afar. The total population (1964) is 82,100, including 32,358 Somali of the Ise (Esa), Habar Awal and Gadabursi clans, 31,975 Afar, 7,271 Arabs, and 7,817 Europeans. Djibouti, the capital, had a population (1962) of 43,682, half of whom were Somali.

Apart from those in Djibouti, the Afar and Somali are essentially a pastoral, nomadic people, moving over wide areas with their flocks of sheep and goats, herds of camels, and in some areas cattle. Both peoples are hardy and extremely individualistic, being organized into kinship groups, which among the Somali are more dispersed than among the Afar. War and feud are common, particularly on account of the acute competition for access to grazing

and water; and compensation is paid between kinship groups according to a standard tariff. The two peoples differ considerably in languages and culture, but both practise polygyny within the limits set by Islamic law and, despite their traditional hostility, some intermarriage takes place between them. Both are Sunni Muslims, mainly of the Shafi'ite rite, although Hanafites are also found among the Afar. In general, Afar society is more hierarchically organized and more closely akin to that of the Arabs than is the Somali social system. Among the Afar the traditional Muslim sultanates are more developed, there is a pervasive class distinction between the Asaimara nobles and the Adoimara tributary commoners, and some age-grade organizations occur.

History.—Although France had gained Obock as early as 1862, it was not until 1888 that the Côte française des Somalis was established and its frontier with the British Somaliland Protectorate defined. In 1897, by treaty with Ethiopia, the territory was somewhat reduced in extent. Djibouti had become the official capital in 1892, and shortly afterward work began on the construction of the railway to the Ethiopian hinterland which reached Dire Dawa in 1903 and connected with Addis Ababa in 1917. Djibouti was thus assured of prosperity, and its population of 15,000 (1925) more than doubled by the 1960s. The interior was opened up between 1924 and 1934 by the construction of roads and administrative posts. After the Italian conquest of Ethiopia in 1936, the territory was heavily fortified, but in 1940 a neutral Vichy regime was established. Thereafter Djibouti was blockaded until the end of 1942 when the Côte declared for Gen. Charles de Gaulle and the Free French. After World War II, despite developments, Djibouti increasingly lost trade to the port of Assab in Eritrea, which was then federated with Ethiopia. To safeguard the economy, Ethiopia was given a larger interest in the railway by a treaty of November 1959.

French Somaliland acquired the status of overseas territory in 1946; since the *loi cadre* ("organic law") of 1956 it has enjoyed internal autonomy. In 1958 the Côte voted to become an overseas territorial member of the French Community under the Fifth Republic. Those who voted in favour were mainly Afar and Europeans; the Somali electorate as a whole either abstained or voted against the continuation of ties with France.

Administration and Social Conditions.—French Somaliland is administered by an Executive Council, presided over by the governor and elected by the Territorial Assembly. The assembly, itself elected, was set up in 1957 with 32 members. The 1958 elections were won by the party for the Défense des Intérêts Économiques et Sociaux du Territoire, and the new Executive Council consisted of four Somali, three Afar, and one European. The territory also elects a representative in both the French National Assembly and the Senate.

Political realignments in the late 1950s led to the formation of two main parties: the Union Démocratique representing the Afar electorate and the Mouvement Populaire, the Somali. In 1962 these joined forces to campaign for independence within the French Community.

Each of the administrative districts (*cercles*), Djibouti, Tadjoura, Ali Sabieh, and Dikhil, is in the charge of a French colonial officer. Government-appointed headmen (*akil*) and local authorities form auxiliary tribunals in the districts, and Islamic law affecting matters of personal status is administered by stipended cadis.

Social and economic development is financed by grants-in-aid from France which provide an annual contribution of about 239,130,000 Djibouti francs. This is used to finance road construction, port development and maintenance, health services, housing, and other urban and rural social services. The Côte has one 550-bed hospital, seven dispensaries, and five rural sanitary posts. In the mid-1960s more than 3,000 pupils attended schools including some that offered postelementary and technical education.

Economy.—Apart from the pastoral resources of the nomads (estimated at 25,000 camels, 700,000 sheep and goats, and 78,000 cattle), the territory's main economic asset is the free port of Djibouti. In the mid-1960s this was entered by more than 2,000 vessels annually and provided port revenues amounting to about 290,000,000 Djibouti fr. The port serves the Ethiopian hinterland

TRANSPORTATION ROUTES OF FRENCH SOMALILAND

to which it is connected by the Addis Ababa railway. The territory's own exports are mainly marine salt (about 6,500 metric tons annually) and hides and skins. The chief imports are cotton yarns and cotton goods, cattle, coal, and sugar. Djibouti Airport is served by international air routes from Europe, East Africa, the Malagasy Republic, the Arabian Peninsula, and the India-Pakistan Subcontinent. Radio Djibouti broadcasts daily in the French, Arabic, Somali, and Afar languages.

Unlike other French overseas territories the Côte does not belong to the franc area. From March 21, 1949, it had a freely convertible currency called the Djibouti franc (100 Djibouti francs = 0.414507 g. of fine gold). This is guaranteed by a deposit in U.S. dollars with the French American Corporation of New York ($1 = 214.39 Djibouti francs) and has a value equivalent to .23 new francs.

SOMALI REPUBLIC (Somalia), a state of northeast Africa formed in 1960 by the union of the former British Somaliland Protectorate and the Italian-administered Trust Territory of Somalia. With an area of 246,154 sq.mi. (637,541 sq.km.), it covers much of the so-called Horn of Africa, extending from the border of French Somaliland along the Gulf of Aden and around the disputed eastern borders of Ethiopia, and down the coast of the Indian Ocean to the Kenya border. The capital is Mogadishu (*q.v.*).

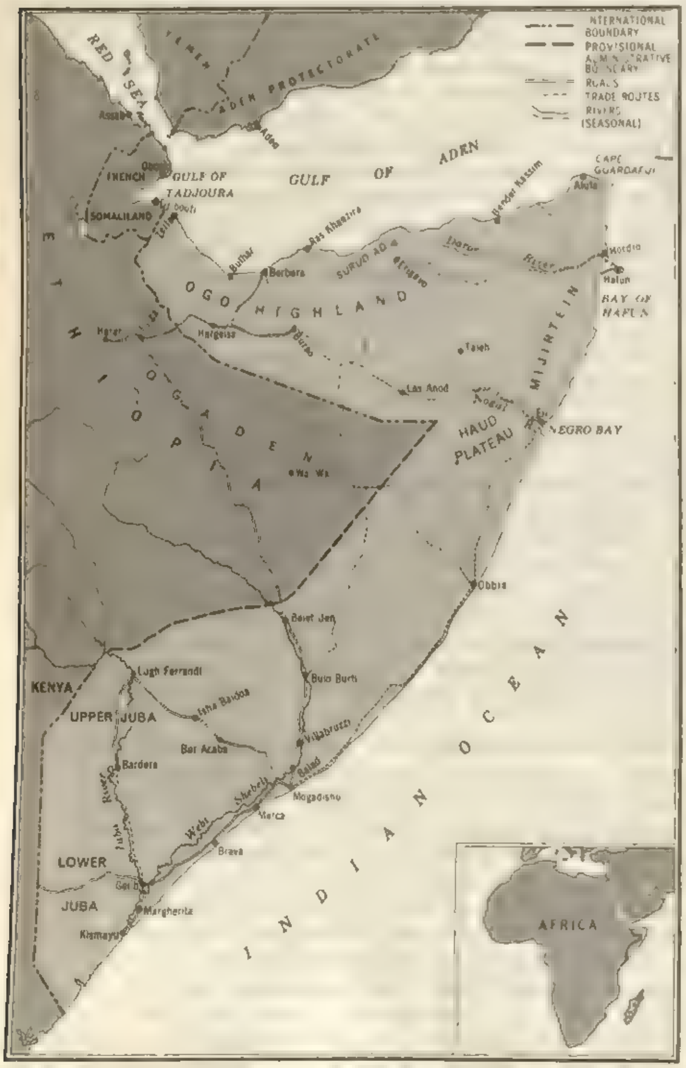
Physical Geography.—As a whole the country presents a harsh environment, part of it being semidesert. The northern coastal plains, which stretch from the Gulf of Tadjoura (Tajura) along the Gulf of Aden into Mijirtein region, are particularly arid, and from their scorched appearance in the dry seasons are known locally as *guban* ("burned"). Inland this barren coastal strip gives place to the maritime range, the Ogo Highland (Surud Ad, near Erigavo, 7,894 ft. [2,406 m.]), running from French Somaliland parallel with the coast and descending gradually southward into the vast tilting Haud Plateau. This plateau has an average height of 3,000 ft. (900 m.) in the centre but rises much higher in the Harar highlands to the west in Ethiopia. The highlands slope gradually and fairly regularly from the northwest and are intersected by

low-lying plains and valleys which are much more widely spaced in the south than in the precipitate north. The Juba River and the Webi Shebeli contain water all the year round and provide the main river system of the whole area. Both rivers descend from the Ethiopian highlands.

The Shebeli, with a total length of about 1,250 mi. (2,000 km.), runs parallel to and north of the Juba through the southern part of the Ogaden to Balad, about 20 mi. (30 km.) from the Indian Ocean, where it turns southwest and, after a further 170 mi. (270 km.), disappears in a series of marshes and sandflats a few miles north of Gelib on the Juba. With exceptionally heavy rain the Shebeli meets the Juba near Margherita and thus enters the sea; otherwise it has no outlet. In the north the largest seasonal streams are the Daror and the Nogal, which run only after heavy rain but contain permanent water in their lower reaches. The Daror enters the Indian Ocean in the Bay of Hafun, and the Nogal farther south in Negro Bay.

Geologically, the plateau consists mainly of gneisses and schists. In the north it is overlaid with red and purple unfossiliferous sandstone, capped near its edge with cherty limestone, also unfossiliferous but possibly of Lower Cretaceous Age. The plains inland from Berbera and the maritime margins between the coast and the foot of the plateau consist of Lower Oölitic limestone.

Climate.—From June to September, especially, the northern coast is unbearably hot and virtually deserted. Berbera and Bender Kassim have average maximum temperatures of 42° C (108° F) and 40° (104°), respectively, with a minimum of 21° (70°). The main wet season is in the cooler months between November and March, but the annual rainfall rarely exceeds 3 in. (77 mm.). Nevertheless, the seasonal freshets which scar the



PRINCIPAL TOWNS AND PHYSIOGRAPHIC REGIONS IN THE SOMALI REPUBLIC

maritime hills facing the Gulf of Aden make water abundant beneath the sandy topsoil. Elsewhere on the plateau water is obtained from wells sunk in dry river valleys, and on high ground it is usually abundant. Some of the inland plains, particularly the Haud, are dry and have little water except in seasonally filled basins. On high ground the rainfall reaches as much as 20 in. (500 mm.), especially in the west, and the climate is pleasant with temperatures considerably lower than along the northern coast.

Compared with the north, the south with its two permanent rivers and their tributaries is relatively well watered. The annual rainfall varies between 13 and 20 in. (330 and 500 mm.) both on the coast and inland. The mean annual temperature on the coast which is very humid in the hot seasons, is about 28° C (82° F), and only a few degrees higher inland. In both northern and southern Somaliland there are two main rainy seasons: *Gu*, falling between March and June, and *Dayr*, between September and December. In the south the hottest period is during March and April, and the coolest from July to August.

Vegetation.—Most of the country is covered by scrub bush, in places almost impenetrably dense, but intersected by wide grassy plains. Vegetation patterns correspond generally to the distribution of saline and nonsaline soils. Along the salty coast the hadun bush or seepweed (*Suaeda*) predominates; and in the lower and saltier parts of the gypseous valleys inland daran (*Limonium* species) abounds. In the more widespread nonsaline areas the most important trees are dosok, one of the box trees (*Buxus hildebrandtii*), and a wide range of acacias. Galol (*Acacia bussei*) is probably the most important tree in northern and central Somaliland. Its long roots provide the framework of the nomadic hut; mats and ropes are made from its bark; the ripe fruit is eaten; and the leaves and young branches are browsed by livestock. It is also used for firewood and charcoal burning. Above 2,000 ft. (600 m.) aloes are plentiful; and in most arid areas of the country the umbrella Euphorbia is common. The Boswellia, which produce frankincense, and other gum-bearing trees flourish in the arid regions of the northeast, particularly in the Erigavo and Mijirtein areas. Some species of figs also occur; and in a few areas above 5,000 ft. (about 1,500 m.) there are small forests of cedar of Lebanon. Along the larger permanent watercourses other trees such as the mangroves and the sycamore fig occur. The commonest grasses are daremo (*Chrysopogon aucheri*), gugangub (*Eragrostis haraensis*), dir (*Andropogon* spp.), and sadehho (*Dactyloctenium* spp.).

Animal Life.—Common among the larger mammals are leopards (widely distributed), hyenas, jackals, foxes, badgers, wild dogs, giraffes (mainly in the south), and a variety of antelopes. The latter include the beisa oryx, the greater and lesser koodoo (kudu), Swayne's hartebeest, waterbuck (mainly in the Shebeli and Juba valleys), Clarke's gazelle (dibatag), Waller's gazelle (gerenuk), Soemmerring's gazelle, the dero (*Gazella speki*), and the extremely common dik-dik or sakaro antelope. The wild ass is plentiful in the north, and the zebra occurs mainly south of the Juba. Lions are found in most parts, but the rhinoceros is rare. There are elephants and hippopotamuses along the Juba and Shebeli, and crocodiles abound in these rivers. There are wart hogs, baboons, a tree monkey, jumping shrews, two varieties of squirrels, a small hare, rock rabbits, stoats, and mongooses. Ostriches are common in open country.

Birds of prey include eagles, vultures, kites, ravens, and the carrion stork. Bustard, guinea fowl, partridge, sand grouse, and wild goose are widely distributed. There are many kinds of snakes, the more dangerous being pythons, puff adders, spitting cobras, and kraits. Scorpions are common after the rains. Mosquitoes, sand flies, houseflies, ticks, and locusts are temporary seasonal pests, usually in limited areas except for mosquitoes near permanent water. Termites are important soil makers except on gypsum.

There are six game reserves in the territory.

The People.—The Somali peoples are classed, largely on linguistic grounds, as southeastern Cushites (*see* CUSHITIC PEOPLES) or Hamites (*q.v.*). Physically they are generally tall and handsome, often quite dark in skin colour, and many have facial

characteristics that suggest an Arab or Semitic strain; this was confirmed by blood-group studies. There has long been trade between Somaliland and Arabia, and Islam is the state religion. The Somali are devout Sunni Muslims, adhering mainly to the Shafi'ite rite. Sufism, the mystical movement of Islam, is well developed among them.

In the arid northern, central, and trans-Juban areas live the Dir, Isaq (Ishaak), Hawiya, and Darod clan-families (the "Samaale," or Somali proper), who are predominantly pastoral nomads. The Digil and Rahanwein ("Sab" groups) live largely as cultivators in the more fertile country between the Shebeli and Juba rivers where they have mixed with earlier Negroid and Bantu settlers and also with Galla (*q.v.*). Some residual Bantu groups remain as cultivators in small enclaves along the rivers and in the hinterland between them. The chief communities of the Shebeli are the Shidle, Kabole, Makanne, and Shebeli; and on the Juba, the Gosha and Gobawein.

Northern Somali is the language of most of the people. Arabic, which is widely understood, is the language of religion and after Italian and English the chief written medium, although a local Somali script, called Osmania, also exists.

The widest difference in social organization occurs between the northern pastoral Samaale groups and the southern cultivating Sab. The former are warlike and frequently driven to feud and violence by competition for scarce grazing and water. A standard indemnity exists for a man's life in the form of blood money (Arabic *dia*, Somali *mag*), rated in most areas at 100 camels. There is also a tariff of compensation for lesser injuries. The basic units of pastoral society are *dia*-paying groups of related agnatic kinsmen, paying and receiving blood money in concert.

Policy decisions are made democratically by all the adult men concerned, and though some of the larger pastoral groups have clan-heads styled sultans, these have little constitutional authority. In contrast, the society of the southern cultivating Sab is more hierarchically organized; chiefs hold greater power and local territorial ties are of more importance in political unity than among the nomads.

The Somali are generally polygamous within the limits of Islamic law; and, among the pastoralists particularly, men like to marry outside their own clan to establish bonds which may be of advantage to them. Although there is no caste structure there are a number of dispersed groups of low status with whom other Somali traditionally do not marry. In the north these are known collectively as *sab*, and in the south where the cleavage is less marked as *bon*. The main groups are the Midgans (leather-workers), the Tumals (blacksmiths), and the Yibirs (soothsayers and pedlars).

History.—*Exploration.*—From their connection with the Ethiopian hinterland, their proximity to Arabia, and their export of precious gums, ostrich feathers, ghee (clarified butter), and other animal produce as well as slaves from farther inland, the northern and eastern Somali coasts have for centuries been open to the outside world. This area probably formed part of Punt, "the land of aromatics and incense," mentioned in ancient Egyptian writings. Between the 7th and 10th centuries, immigrant Muslim Arabs and Persians developed a series of trading posts along the Gulf of Aden and Indian Ocean coasts. Many of the early Arab geographers mentioned these and the sultanates that grew out of them, but they rarely described the interior of the country in detail. In fact intensive exploration really began only after the occupation of Aden by the British in 1839 and the ensuing scramble for Somali possessions by Britain, France, and Italy (see *The Imperial Partition* below). In 1854, while R. F. Burton (later Sir Richard) was exploring the country to the northwest in the course of his famous journey from Berbera to Harar, his colleague J. H. Speke was making his way along the Makhir Coast in the northeast. This region had previously been visited by Charles Guillain, captain of the brig "Ducouedid," between 1846 and 1848. Guillain also sailed down the Indian Ocean coast and went ashore at Mogadishu, Merca, and Brava, penetrating some distance inland and collecting valuable geographical and ethnographic information. In 1865 the German explorer Baron Karl Klaus von der Decken sailed up the Juba River as far as Bardera in the small steamship "Welf" which foundered in rapids above the town. Decken was killed by Somali but much valuable information collected by his expedition survived.

In 1883 a party of Englishmen (F. L. and W. D. James, G. P. V. Aylmer, and E. Lort-Phillips) penetrated from Berbera as far as the Shebeli, and between 1886 and 1892 H. G. C. and E. J. E. Swayne surveyed the country between the coast and the Shebeli and also reached farther east toward the Nogal Valley. During 1894–95 A. Donaldson-Smith explored the headwaters of the Shebeli, reached Lake Rudolf, and eventually descended the Tana River to the sea. In 1891 the Italian Luigi Robecchi-Bricchetti trekked from Mogadishu to Obbia, and then crossed the Ogaden to Berbera. About the same time further explorations were made by another Italian, Capt. Vittorio Bottego. In the 20th century several extensive surveys were made, especially in the former British Protectorate, by J. A. Hunt between 1944 and 1950, and much of the country was mapped by aerial survey.

The Coast and Hinterland Before Partition.—Until recent times the history of the Horn of Africa had been dominated by two great themes: the southward expansion of the Somali from the Gulf of Aden littoral; and the development by Arab and Persian Muslim settlers of a ring of coastal trading towns dating from at least the 10th century A.D. By this time Islam was firmly established in the northern ports of Zeila and Berbera; and at Merca, Brava, and Mogadishu on the Indian Ocean coast in the south. These centres were engaged in a lively trade, with connections as far afield as China. Initially the trend of pressure was from these coastal centres inland, especially in the north.

Probably by the 10th century the country from the Gulf of Aden coast inland was occupied first by Somali nomads and then, to their south and west, by various groups of pastoral Galla who, apparently, had expanded from their traditional homelands in southwest Ethiopia. To the south of these Hamitic Somali and Galla—the "Berberi" of classical times and of the Arab geographers—the fertile lands between the Shebeli and Juba rivers were occupied, partly at least, by sedentary Bantu tribes of the Nyika confederacy whose ancient capital was Shungwaya. Remnants of these Zanj, as they were known to the Arab geographers, still survive in this region; but their strongest contemporary representatives are found among the northeastern coastal Bantu of whom the Pokomo live along the Tana River in northern Kenya. Another smaller allied population consisted of the ancestors of the scattered bands of hunters of northern Kenya and Jubaland known as Wa-Ribi or Wa-Boni, a people whose appearance and mode of existence recall those of the Bushmen of other areas of Africa.

With this distribution of peoples in the 10th century, the stage was set for the great movements of expansion of the Somali toward the south and of the Galla to the south and west. The first known major impetus to Somali migration was the arrival (*c.* 11th century) of Sheikh Ismail Jabarti, ancestor of the Darod Somali, who came from Arabia to settle in the northeast corner of the Somali Peninsula. This was followed, perhaps two centuries later, by the settlement of Sheikh Isaq, founder of the Isaq Somali. As the Darod and Isaq clans grew in numbers and territory in the northeast, they began to vie with each other, with earlier Somali groups, and with their Galla neighbours, thus creating a general thrust toward the south and west. By the 16th century the movements which followed seem to have established much of the present distribution of Somali clans in northern Somaliland. Other Somali pressed farther south, and some, according to the Arab geographer Ibn Said, had already reached the region of Merca by as early as the 13th century.

In the meantime, farther to the west, a ring of militant Muslim sultanates had grown up around the Christian kingdom of Abyssinia and the two sides were engaged in a protracted struggle for supremacy. Somali clansmen regularly formed part of the Muslim armies: the name "Somali" first occurs in an Abyssinian song of victory early in the 15th century. In the 16th century the Muslim state of Adal, whose port was Zeila, assumed the lead in the holy wars against the Christian Amhara. The turning point in the struggle between Christians and Muslims was reached with the Abyssinian victory in 1542, with Portuguese support, over the remarkable Muslim leader Mohammed Grañ, who, with his Somali

armies, had harried Abyssinia almost to the point of collapse. This victory, which saved Abyssinia, also closed the door to Somali expansion westward and increased the pressure of the Somali and Galla thrust south. With this stimulus, the main mass of the Galla swept into Ethiopia from the south and southwest, and streamed in conquering hordes as far north as the ancient city of Harar, which was laid waste in 1567.

This massive invasion left something of a political vacuum in the south of the horn that new Somali settlers were quick to fill. By the 17th century, the influx of new migrants, competing and jostling with each other, had become considerable. The old Ajuran Somali sultanate, linked with the port of Mogadishu, was overthrown and Mogadishu itself invaded and split into two rival quarters. Some of the earlier Somali groups found refuge in northern Kenya. The continuing Somali thrust south—largely at the expense of Galla and Zanj predecessors—was ultimately only effectively halted at the Tana River by the establishment of administrative posts about 1912.

Thus by the latter part of the 19th century the coastal and hinterland traditions had merged and the centre of pressure had swung from the coast to the interior. In the north, the ancient ports of Berbera and Zeila, much reduced in prosperity and importance, were now controlled by Somali nomads and the position with the old ports of Merca, Brava, and Mogadishu was very similar. These towns had all been penetrated by various Somali clans and the dominant political influence became that exercised by the Geledi clan ruling the lower reaches of the Shebeli. Commercial and political links which provided an opening for European infiltration had, however, also been forged between these two coasts and the outside world. Part of the northern Somali coast including Zeila was then nominally under Turkish suzerainty, the Turkish claim going back to the 16th century when Turkish forces had aided Mohammed Grañ in his campaigns against Ethiopia. The southern coastal towns, on the other hand, acknowledged the overlordship of the sultan of Zanzibar, although the latter's authority was slight in comparison with that exercised locally by the Geledi Somalis.

The Imperial Partition.—About the middle of the 19th century the Somali Peninsula became a theatre of competition between Great Britain, Italy, and France. On the African continent itself Egypt was also involved, and later Abyssinia, expanding and consolidating its realm under the guiding genius of Menelik (later emperor of Ethiopia). Britain's interest in the northern Somali coast followed the establishment (1839) of the British coaling station at Aden on the short route to India. The Aden garrison relied upon the importation of meat from the adjacent Somali coast. France sought its own coaling station and obtained Obock on the Danakil coast in 1862, later thrusting eastward and developing the Somali port of Djibouti. Farther north, Italy opened a station in 1869 at Assab which with later acquisitions became the colony of Eritrea. Stimulated by these European maneuvers, Egypt revived Turkey's ancient claims to the Red Sea coast. In 1870 the Egyptian flag was raised at Bulhar and Berbera.

Britain at first protested these Egyptian moves, but by 1877 had come to regard the Egyptian occupation as a convenient bulwark against the encroachments of European rivals. With the disorganization caused by the revolt in the Sudan, however, Egypt was obliged to curtail its colonial responsibilities, and evacuated Harar and its Somali possessions in 1885. In these circumstances, the British government reluctantly decided to fill the gap left by Egypt. Between 1884 and 1886, accordingly, treaties of protection were drawn up with the main northern Somali clans guaranteeing them their "independence." Somali territory was not fully ceded to Britain, but a British protectorate was proclaimed and vice-consuls appointed to maintain order and control trade at Zeila, Berbera, and Bulhar. The interior of the country was left undisturbed, only the coast being affected.

Meanwhile, France had been assiduously extending its colony from Obock and a clash with Britain was only narrowly averted when an Anglo-French agreement on the boundaries of the two powers' Somali possessions was signed in 1888. In the same period the Italians were also actively extending their Eritrean colony and encroaching upon Ethiopian territory. Not to be outdone Menelik took the opportunity of seizing the Muslim city of Harar, left independent after the Egyptian withdrawal. In 1889 Ethiopia and Italy concluded the Treaty of Uccialli, which in the Italian view established an Italian protectorate over Ethiopia. Arms and capital were poured into the country and Menelik was able to apply these new resources to bring pressure to bear on the Somali clansmen around Harar. In 1889 Italy also acquired two protectorates in the northeast corner of Somaliland; and by the end of the year the southern part of the Somali coast leased by the British East Africa Company from the sultan of Zanzibar was sublet to an Italian company.

Italy had thus acquired a Somali colony. From 1892 the lease was held directly from Zanzibar for an annual rent of 160,000 rupees, and after the failure of two Italian companies by 1905, the Italian government assumed direct responsibility for its colony of Somalia. To the south of the Juba River the British East Africa Company held Jubaland until 1895, when this became part of Britain's East Africa Protectorate. Britain and Italy reached agreement in 1884 on the extent of their respective Somali territories, but the Battle of Aduwa (1896), at which the infiltrating Italian armies were crushingly defeated by Ethiopian forces, radically changed the position. Ethiopia, then independent of Italy, was plainly master of the hinterland, and in 1896–97 Italy, France, and Britain all signed treaties with the new emperor Menelik, curtailing their Somali possessions. Italy gave up the Somali Ogaden, and Britain excised much of the western Haud from its protectorate. Although the land and Somali clansmen (who were not consulted), so abandoned, were not recognized as belonging to Ethiopia, there was nothing then to stop their gradual acquisition by Ethiopia.

These arrangements had scarcely been completed when the British Somaliland Protectorate administration found its modest rule threatened by the religious rebellion led by Mohammed bin Abdullah Hassan. This Somali sheikh (known to the British as the "Mad Mullah") of the Ogaden clan, living with his mother's people in the east of the Protectorate, was an adherent of the Salihiya religious order whose reformist message he preached with messianic zeal. He quickly achieved wide recognition for his learning, piety, and skill as a mediator, and initially cooperated with the authorities. In 1899, however, Sheikh Mohammed came into conflict with the recently established Christian mission, and was also involved in a petty dispute with the administration. With the current European and Ethiopian encroachment, and with the example of the Sudanese mahdi, these two incidents provided the seeds which rapidly developed into a major Somali insurrection.

Sheikh Mohammed assumed the title of sayyid (not of mahdi) and his followers were known as the dervishes. He displayed great skill in employing all the traditional tactics of Somali clan politics in building up his following, strengthening these with the call to national Muslim solidarity against the infidel colonizers. Arms and ammunition, denied to Somalis in the past, became easily available through the ports of Djibouti and the northeastern coast, and the dervishes, although opposed by many Somalis who were branded as traitors to Islam, successfully weathered four major English campaigns between 1900 and 1904. The cumbersome British armies, hampered by their supply and water requirements, found the dervish guerrilla tactics hard to combat effectively, and when in 1910 the British government decided to abandon its inconclusive and extremely expensive operations and withdrew to the coast leaving chaos in the interior, Sayyid Mohammed seemed to have gained the day. A new policy was subsequently adopted, however, and with the aid of an increasingly effective camel constabulary (whose founder, Richard Corfield, was killed at the Battle of Dul Madobe in 1913), the dervishes were kept at bay until 1920, when a combined air, sea, and land operation finally routed them. The formidable dervish stronghold at Taleh was bombed but the sayyid escaped, as so often before, only to die of influenza a few months later while desperately seeking to rally his scattered followers.

After 1920 administrative control (under the colonial office since 1905) was gradually restored in the protectorate. In So-

malia, where the Italians had been gradually extending their hold on the country, the sayyid's rebellion had caused less disruption, and the appointment in 1923 of the first fascist governor marked a new positive phase in the life of the colony. Two years later, Britain ceded Jubaland with the port of Kismayu (Chisimaio); and in 1926, after a bitter military campaign, the two northern Italian protectorates were firmly incorporated. Italian settlement was encouraged, and fruit plantations were developed along the Shebeli and Juba valleys. Although agreements of 1897 and 1908 had defined the border with Ethiopia, this had not been demarcated, except for a stretch of about 18 mi. (28 km.) delimited in 1910, and remained in dispute, thus facilitating the gradual Italian infiltration into Ethiopia. In 1934 the celebrated Walwal incident (*see* ETHIOPIA: *History*) occurred in the eastern part of the Ogaden claimed by both Italy and Ethiopia. The Italian conquest of Ethiopia which followed brought the Ethiopian and Italian Somali territories together within the framework of Italy's short-lived East African empire.

Establishment of the Somali Republic.—During World War II the British Protectorate was evacuated (1940) but was recaptured with Italian Somalia in 1941 when Ethiopia was also liberated. With the exception of French Somaliland, all the Somali territories were then united under British military administration. In 1948 the Protectorate reverted to the colonial office; the Ogaden and the Haud were gradually surrendered to Ethiopia; and in 1950 the Italians returned to Somalia with ten years to prepare the country for independence under UN trusteeship.

Taking advantage of the modest progress which the British military administration had effected, social and political advancement was rapidly pursued, although economic development proved much more difficult. The effect of these changes was naturally felt also in the British Protectorate which, in the event, became independent on June 26, 1960. On July 1 Somalia followed suit and the two territories joined to form the Somali Republic.

Prior to independence the grazing movements of nomads into Ethiopian territory were recognized by the Anglo-Ethiopian Treaty of 1897 and the agreement of 1954, but the Somali government refused to take over the treaty since it did not recognize Ethiopia's rights to these grazing lands.

The dispute over this question caused relations with Ethiopia to remain strained in the early 1960s, although with the independence of Kenya, interest also focused on the future of the Somali-inhabited northeastern areas of Kenya. The Northern Frontier District Commission of October 1962 established that most of the tribesmen in these areas wished to join the Somali Republic. The failure of the 1963 Kenya constitution to meet this desire led the Somali inhabitants to boycott the Kenya elections and the Somali Republic to sever diplomatic relations with the U.K. In pan-African and international affairs the republic pursued a moderate policy seeking to maintain strict neutrality. In 1961 delegates attended the third All Africa Peoples Conference in Cairo and the Monrovia and Belgrade conferences. At the Addis Ababa Conference in February 1962 the republic indicated its desire to join an East African federation of African states.

Population.—Censuses of population have been attempted in parts of the Somali Republic but because of the difficulties and expense involved in enumerating a largely nomadic people they have not been completed. The Somali population (1963 est.) totals 2,250,000. This estimate gives an overall Somali density of about nine persons per square mile (over three per square kilometre), but in parts of the country, such as the Mijirtein region, the density falls to less than half that figure. There are also about 80,000 somalized Bantu and Negroid inhabitants, concentrated between the two main rivers, about 40,000 Arab, Persian, Indian, Pakistani, Eritrean, and Ethiopian immigrants, and about 4,500 Europeans, mainly Italian.

By clan-family the Somali population is divided approximately as follows: Darod 750,000; Hawiya 520,000; Isaq 400,000; Dir 150,000; Digil and Rahanwein 430,000. Despite a high incidence of tuberculosis, and seasonal malaria, the population was increasing in the mid-20th century. A net reproduction rate of 1.3 was calculated from data on the municipal populations of the south.

The largest towns, with 1965 estimates of population, [illegible] Mogadishu, capital of the republic (127,119); Merca [illegible] and Hargeisa [illegible] and Berbera [illegible] 219), capital and port of the Northern region, respectivel[illegible]

Administration.—The Somali Republic is a democratic unitary state. The president, the head of state, is elected for six years by the National Assembly, and he selects from its members a prime minister to form a government. The prime m[illegible] sisted by a Council of Ministers. With independence [illegible] Legislative Council of the Protectorate was joined to the [illegible]tive Assembly at Mogadishu to form a unitary National Assembly this has 123 members. Although legislative government was introduced in Somalia only in 1956 and in the protectorate in 1957, the political parties have a longer history. The party with the widest following is the Somali Youth League, formed in 1943 during the British military administration of Somalia. This party won the elections in Somalia in 1959 and, on the unification of the two territories, formed a coalition government with the Somaliland National League and the United Somali Party, the parties then in power in the protectorate. The government, which represents all the main clan and tribal groupings in the republic, is concerned to promote the full realization of the "Greater Somalia" ideal—the further union of the republic with the remaining Somali territories, French Somaliland, Ethiopian Somaliland, and the Northern Province of Kenya. Of these, Harar province of Ethiopia contains the largest number of Somali (about 500,000). Voters in a referendum held in June 1961 approved the provisional constitution (framed by the government of the former Italian Trust Territory before its union with British Somaliland) by a large majority—1,760,540 in favour and 182,911 opposed. However, voters in former British Somaliland opposed it 54,284 to 49,527. In the national elections held in March 1964 the Somali Youth League returned to power with 69 seats.

Local Government.—The republic is divided into eight regions: Western (Hargeisa), Eastern (Burao), Mijirtein (Migiurtina), Mudugh, Hiran, Benadir, Upper Juba (Alto Giuba), and Lower Juba (Bassa Giuba), each divided into administrative districts. Control is exercised from district headquarters through stipended headmen, local authorities (*akils*), or recognized chiefs (sultans). However, because of the traditional absence of strong chiefly authority, the system of administration is in practice direct rather than indirect, except in the arable areas of the south. District, municipal, and semiurban councils exist throughout the republic, but these have developed fiscal, executive, and legislative powers more effectively in the towns and certain agricultural areas than in the nomadic areas.

Living Conditions and Social Services.—In the 1960s United Nations community development plans were in progress. Health services were rapidly expanded despite a continued lack of doctors. Member states of the European Economic Community (EEC) built and equipped a modern 800-bed hospital near Mogadishu; two rural 50-bed hospitals were being built by Soviet engineers. The fight against tuberculosis, one of the most serious scourges in the country, was intensified and a new tuberculosis centre was opened with WHO aid in Mogadishu in 1961. The control of seasonal malaria was also improving through extended antimalaria services.

Justice.—Although the administration of justice is primarily the function of the judiciary, subject to the minister of justice, administrative officials in charge of districts and regions sometimes have also to act as magistrates. The operation of the official penal code is to some extent modified by the existence of the customary *dia*-paying group agreements which help to define the legal status of the individual in a dispute. A religious judiciary also exists in the form of government-appointed *qadis* administering the Shari'ah (mainly the Shafi'ite code) in matters of personal status such as marriage, divorce, inheritance (in the towns), and the assessment of physical injuries. This last function is important in a country where, particularly among the nomads, physical violence is not uncommon. Normally, however, although the *qadis* [illegible] compensation for injuries, the resulting claims for damag[illegible] dea[illegible] with by the secular courts.

A serious difficulty was the existence of two separate legal codes, that established by the British in the Northern regions and that by the Italians in the south. With UN expert advice a new legal code was drafted amalgamating and modifying the laws. An excellent police force was built up on the basis of the British-trained force of the former protectorate and that trained by the Italians in the south. This was fully integrated under a southern Somali commandant and northern Somali deputy. The U.S., Italy, and Britain assisted in the further training and equipping of the force.

Education.—There are about 400 elementary, intermediate, and assisted Koranic schools, but few secondary schools. The school of politics and administration, opened at Mogadishu in 1950, was transformed in 1957 into a technical and commercial institute. A higher institute of law, economics, and social studies was founded in 1954, providing a two-year Rome University diploma course, and in 1960 became a university institute charged with coordinating higher education throughout the country. In the 1960s this was being further developed to provide a wider range of courses. Other developments included a secondary boarding school in Mogadishu, built with Soviet aid, and a teacher training institute at Afgoi built with American aid. Egypt has also provided funds for schools and in the mid-1960s there were about 200 Egyptian teachers in the republic, the Egyptian government's main contribution to education. Several hundred Somali students attend overseas universities and technical institutes in Communist and Western countries. In the south, where Italian was formerly the most-favoured foreign language, English has been increasingly taught. It is estimated, however, that more than 90% of the population remains illiterate.

Defense.—A small but impressive national army, equipped with Egyptian, British, Russian, and Italian aid, was formed from the Somali Scouts (the military establishment of the former protectorate) and certain Italian-trained police units in Somalia. In the mid-1960s it was planned to enlarge and modernize the Army and build up the Air Force with Soviet aid.

The Economy.—This is largely a subsistence economy although livestock, hides, and skins have long been exported, and cash crops were introduced by the Italians. The Somali are chiefly a nomadic, pastoral people. More than two-thirds are pastoralists, some of whom practise subsidiary cultivation; about one-sixth are engaged in sedentary agriculture; and the remainder are occupied in commerce, industry, fishing, and the government service.

Livestock.—The pastoralists move widely in search of grazing for their flocks of sheep and goats and herds of camels, and also cattle in some cultivated areas, especially in the western part of the Northern regions and in the south between the Juba and Shebeli, except in tsetse-infected areas along the rivers. Since in the dry seasons sheep, goats, and cattle require watering every few days, they are herded and managed separately from the camels, which can go without water for many days. Small groups of families, each consisting of a man, his wife or wives, their unmarried daughters, and infant sons, move with their flocks and burden camels, setting up camp in areas of pasture within easy reach of water. The grazing camels, herded by boys from the age of about six years upward and young unmarried men, are often several hundred miles distant from the nomadic camps with their flocks, especially in the dry seasons, and the two herding groups move through the pastures to a great extent independently of each other. Prescriptive rights are generally not asserted to pasturage, and people move with their stock according to the rhythm of the seasons and the availability of grass and water and in accordance with the pattern of relations between groups. In the dry seasons people and stock are concentrated near the wells, competition for access to which is often so acute that fighting results; but in the rainy seasons more dispersed grazing patterns are assumed.

Crops.—In the western part of the Northern regions about 140,000 ac. (56,650 ha.) are tilled, the main crop being sorghum sown after the *Gu* rains of April and May and harvested about September or October. The country's most important agricultural area, however, is that between the Juba and Shebeli rivers, occupied principally by the Digil and Rahanwein tribes. About 30,000 sq.mi. (77,700 sq.km.) are estimated to be suitable for cultivation, but only about one-tenth of this area is exploited. The southern crops are cereals, durra, beans, finger millet (*Eleusine coracana*), sesame, cotton, manioc, papaya, bananas, and some other fruits. In the regions of black alluvial soil along the rivers where tsetse fly militates against mixed farming, and in the high plateau region behind the *Doi*, durra and maize (corn) are the chief crops; and in the red and white soils durra, millets, sesame, sweet potatoes, and manioc predominate. Traditionally, southern cultivation is by hoe, in contrast to the north where the cultivators use a local form of plow, and there are two durra crops, one sown in May and harvested in August and the second sown in September or October for harvesting about four months later. Yields are said to average 7–9 cwt. an acre.

The chief export crop is the banana, grown by a number of Italian and Somali concessionaires and sold mainly to Italy; in the mid-1960s the market was widening. Italian plantations and Somali farmers in association with Italian concessionaires also produce cotton for export. The production of sugar by a Somali government–Italian consortium on the Shebeli meets most of the country's needs; this has been under expansion.

Development Plans and Industries.—Agricultural and irrigation development plans were initiated after World War II, especially between the Juba and Shebeli rivers, and in the sorghum-growing areas of the Northern regions. In the first area a large-scale UN Special Fund hydrological and resources survey was begun in 1962, and in the Northern regions a mechanized cultivation project was launched in the Tug Wajale plain in 1960. Water-drilling and pastoral betterment projects and the extension of veterinary services were undertaken among the nomads who were being encouraged to move less extensively. Egypt was providing an abattoir and a weaving and spinning factory and was promoting new sugar and cement industries. The U.S.S.R. was financing the creation of a cotton ginnery, a meat- and fish-canning factory, and a dairy produce factory. The banana industry subsidized by Italy was expanded and improved. Iron ore deposits were utilized with UN assistance, and the vast gypsum deposits near Berbera, with the aid of hydroelectric power, offered considerable potential. Oil prospecting (a main field of private investment) and the search for minerals continued. Established minor local industries produced alcohol, edible oil, preserves, food-paste, canned meats and fish, mineral waters (soft drinks), shoes, furniture, chemicals, and mechanical appliances as well as electricity. In 1963 a five-year development plan was inaugurated with a budget of So.Sh.1,400,000,000.

Trade and Finance.—The main exports are bananas, livestock on the hoof, hides and skins, gums, cereals, and cotton. Since independence the livestock industry has steadily improved and banana exports have also increased. In the mid-1960s the total annual value of exports was So.Sh.180,200,000, while imports were valued at about So.Sh.270,800,000 and consisted chiefly of foodstuffs, textile, and mechanized equipment. The bulk of trade is with Italy.

Although in the mid-1960s the republic was still dependent upon Italy and Britain for budgetary aid (as well as for development aid), it was anticipated that fiscal and accounting improvements and vigorous control of public expenditure would soon make it possible to balance the national budget. Foreign aid from both the Western and Communist blocs and from neutral countries was being coordinated by a central planning commission.

The official unit of currency is the Somali shilling divided into 100 cents: 7.14 So.Sh. = U.S. $1; 20 So.Sh. = 1 pound sterling. The Credito Somalo acts as a development bank; there is also a national bank and branches of the banks of Italy, Rome, and Naples, and of National and Grindlays Bank.

Communications.—There are no railways in the republic. EEC funds were used in the early 1960s to build tarmac roads to link the ports of Merca and Kismayu with the nearby banana plantations. Work began on a $7,000,000 U.S. development project to improve Kismayu's harbour facilities, and the port of Mogadishu was also extended. In the mid-1960s international grants and credits were to provide for the development of roads. Hargeisa and Mogadishu are linked by Aden Airways, while smaller local centres are served by irregular police flights. Somalia Aviation

(state owned) operates internal passenger and cargo services. Since independence the scope of information services and broadcasting has widened. Radio Somali at Mogadishu and Hargeisa broadcasts in Somali, Arabic, Italian, and English and there are public radio sets in towns and villages.

SOMASCHI (ORDO CLERICORUM REGULARIUM A SOMASCHA; C.R.S.), a Roman Catholic order of clerks regular, following the rule of St. Augustine, founded in 1528 by St. Jerome Emiliani to work among the poor. It was approved in 1540. The Somaschi conduct schools and orphanages, mainly in Italy.

SOMBOR, a town in the autonomous region of Vojvodina, in the Socialist Republic of Serbia, Yugoslavia, lies east of the Danube near the Hungarian border, 34 mi. (55 km.) SW of Subotica. Pop. (1961) 37,802. The town is a junction of seven railways, an important agricultural centre, and has minor industries. Sombor was occupied by the Turks in 1552. After a century and a half of Turkish rule, it became a fortress of the Habsburg military frontier. From 1747 it became a free town; it was severely damaged in 1848–49 during the Hungarian Revolution; since 1918 it has been part of Yugoslavia, though during World War II it was occupied by the Hungarians. (V. DE.)

SOMERS, JOHN SOMERS (SOMMERS), BARON (1651–1716), English statesman and lawyer, lord chancellor of England from 1697 to 1700, was born on March 4, 1651, near Worcester, the son of John Somers, an attorney. Educated at Trinity College, Oxford, he studied law under Sir Francis Winnington, and in the 1670s associated himself with the leaders of the Country Party, especially with the earl of Essex, William Russell, and Algernon Sidney, but he never entered into their plans so far as to commit himself beyond recall. Algernon Sidney's *Just and Modest Vindication of the Two Last Parliaments* (1681) was attributed to Somers, and he may have assisted in the final drafting. His part as junior counsel in the successful defense of the seven bishops (June 1688) made his reputation. After the Revolution in November 1688 he was elected for Worcester to the Convention Parliament in January 1689. One of the managers for the Commons in the conferences between the two Houses, he was instrumental in persuading the Lords to accept the statement that James II had "abdicated" (not "vacated") the throne. He was chairman of the committee which drew up the Bill of Rights (1689), and is usually credited with a major share in its composition.

Somers was made solicitor general in May 1689 and was knighted in October. He was chairman of the select committee on the Corporation Bill (1690) for the restoration of the borough charters forfeited to Charles II and James II. During the next three years he became closely associated with Edward Russell (afterward earl of Orford), Thomas Wharton, and Charles Montague (afterward earl of Halifax), who with him were to comprise the future Whig Junto; in May 1692 he was appointed attorney general, and in March 1693 lord keeper of the great seal. With the disgrace of the duke of Leeds in 1695 and the virtual retirement of the duke of Shrewsbury in 1696, Somers emerged as the king's chief minister, the leader of the Junto, and the spokesman of Whig opinion in general. His prestige was enhanced by his sweetness of character, combined with strength, and his reputation for disinterestedness. In 1696 he pushed through an act of association which enabled him to purge local government of the more inveterate Tory gentry, and in 1697 he was appointed lord chancellor with the title of Baron Somers of Evesham.

But with the coming of peace with France, by the Treaty of Rijswijk in 1697, the Junto ministry began to break up, and in 1698 and 1699 Somers' relations with William III became increasingly strained. Meanwhile the Commons opposition harried him unmercifully, especially for his grant of a privateering licence to the notorious Capt. William Kidd and his investment in Kidd's expedition to New England. All attempts to remove Somers by parliamentary vote failed, but on April 17, 1700, at the end of the stormiest session of the reign, he resigned at William's command. In April 1701 he was impeached by the Commons for his share in the negotiations which led to the treaty of 1698 for the partition of the Spanish Empire. He defended himself most ably before the House and the charges were dismissed by the Lords in June. Later that year William asked him to form another ministry, but these plans were dashed by the king's death in March 1702.

In the reign of Anne, Somers and the other Junto peers cooperated with the Marlborough-Godolphin government. In 1706 he was one of the managers of the negotiations which resulted in the union with Scotland (1707), and in November 1708, as part of the price for the Junto's continued support of the ministry, he was made lord president of the council. He won over Queen Anne, who had hitherto detested him, but he resigned with the other Whigs on Godolphin's dismissal in September 1710. On George I's accession (August 1714) he was at once reappointed to the Privy Council, but he was too ill to attend regularly, let alone accept the high office that would have been his for the asking. Unmarried, Somers died at his villa, Brookmans, near North Mimms, Hertfordshire, on April 26, 1716, and his title became extinct. His works, which included a few poems, several pamphlets, and an authoritative treatise on the succession to the crown, are listed in H. Walpole, *A Catalogue of the Royal and Noble Authors of England*, volume ii (1758). Most of Somers' papers were accidentally destroyed later in the 18th century.

SOMERSET, EARLS AND DUKES OF, English titles held in the later Middle Ages by members of the Beaufort family and since 1660 by the descendants of Edward Seymour, duke of Somerset, known as the Protector.

WILLIAM DE MOHUN (d. in or before 1155), lord of Dunster, was heir and possibly grandson of William de Moion, seigneur of Moion or Moyon in the Cotentin, Normandy, who went to England in or after 1066 and became sheriff of Somerset (1084 and 1086). He was created earl of Somerset by the empress Matilda in 1141, and apparently supported her throughout the civil war. Stephen, however, did not recognize William's earldom and no new charter was granted by Henry II. William was sometimes also called earl of Dorset, since the two shires were once administered by one sheriff.

The earldom of Somerset in the Beaufort family dated from February 1397, when it was granted by Richard II to JOHN BEAUFORT (*c.* 1371–1410), eldest of the three sons of John of Gaunt, duke of Lancaster, by his liaison with Catherine Swynford. He was succeeded in turn by his three sons, HENRY (1401–1418), JOHN (1404–1444), created duke of Somerset in 1443, and EDMUND (1406–1455), created duke of Somerset in 1448 (*see* SOMERSET, EDMUND BEAUFORT). The family were staunch Lancas-

trians, and Edmund's son Henry (1436–1464) was attainted (1461) under Edward IV. His brother Edmund (*c.* 1439–1471), thus "duke of Somerset" to Lancastrians only, was himself attainted (1465). On his execution (May 6, 1471) after the Battle of Tewkesbury, the male line became extinct. (For details of the careers of the Beaufort earls and dukes, *see* Beaufort.)

The title of duke of Somerset was next held by Henry Fitzroy (*c.* 1519–1536), illegitimate son of King Henry VIII, who was created earl of Nottingham, duke of Richmond, and duke of Somerset in June 1525. He died without issue.

Edward Seymour (*c.* 1500–1552), duke of Somerset, known as Protector Somerset, was the first of the line of dukes to which the present holder of the title belongs. Brother of Henry VIII's third wife, Jane, and uncle of Edward VI, he was created Viscount Beauchamp of Hache (in Somerset) in 1536; earl of Hertford in 1537; and in 1547 Baron Seymour and duke of Somerset (*see* Somerset, Edward Seymour, 1st Duke of). His honours, which were entailed on the issue of his second marriage in priority to that of his first, were forfeited by attainder in 1552. In 1613 Robert Carr (*c.* 1587–1645), favourite of James I, already (1611) Viscount Rochester, was created earl of Somerset (*see* Somerset, Robert Carr, Earl of). On his death without male issue his titles became extinct.

In September 1660 the titles of Baron Seymour and duke of Somerset were restored to William Seymour (1587–1660), great-grandson of the Protector. In 1621 he had inherited the titles of earl of Hertford and Baron Beauchamp which had been granted to his grandfather Edward Seymour in 1559 and he was himself created marquess of Hertford in 1641. In 1610 he had incurred the serious displeasure of James I by his marriage with Arabella Stuart, the king's cousin. Both were imprisoned, but William made a successful escape, remaining abroad until after Arabella's death (1615). All but John, the youngest of his five sons by his second marriage, predeceased him; he was succeeded by his grandson William (1652–1671), 3rd duke of Somerset. William died unmarried and his uncle John (*c.* 1628–1675) became 4th duke. As John died without issue, the marquessate of Hertford became extinct and his cousin Francis Seymour (1658–1678), 2nd Baron Seymour of Trowbridge, grandson of a younger brother of the 2nd duke, became 5th duke of Somerset. Francis, who died unmarried, was succeeded by his brother Charles (1662–1748), known as "the Proud Duke." His marriage (1682) with Elizabeth, sole heiress of Joceline, 11th duke of Northumberland, brought him immense estates, including Alnwick Castle in Northumberland, Petworth, Sussex, Syon House in Middlesex, and Northumberland House in London. He held household appointments under Charles II and James II, but bore arms for William of Orange (afterward William III). In the memorable crisis when Queen Anne was at the point of death, Somerset, acting with the dukes of Argyll and Shrewsbury, secured the Hanoverian succession to the crown. His son Algernon (1684–1750), 7th duke, fought (1708–11) in Flanders during the War of the Spanish Succession. He had no sons, and was created (October 1749) Baron Warkworth of Warkworth Castle, Northumberland, and earl of Northumberland with special remainder to his son-in-law, Sir Hugh Smithson, bart., and to his heirs male by Somerset's daughter Elizabeth. On the 7th duke's death the earldom of Hertford and the baronies of Beauchamp and Seymour of Trowbridge became extinct. The dukedom of Somerset and the barony of Seymour passed to the heir male, Sir Edward Seymour, 6th bart. (1695–1757), 8th duke, a descendant of the Protector by his first marriage, the issue of which had been excluded from succession to the titles and estates until after the failure of the issue by his second marriage (*see* above). The 8th duke's sons, Edward (1718–1792) and Webb (1718–1793), succeeded in turn, as 9th and 10th dukes. The 11th duke, Edward Adolphus (1775–1855), third but first surviving son of Webb, changed his name from Seymour to St. Maur. His son, another Edward Adolphus (1804–1885), 12th duke, held many minor posts in Liberal governments, and was first lord of the admiralty from 1859 to 1866. Leaving no male issue, he was succeeded in turn by his brothers Archibald Henry Algernon (1810–1891) and Algernon Percy Banks (1813–1894), 13th and 14th dukes, and then by Algernon St. Maur (1846–1923), son of the 14th duke. The 15th duke died without issue and the 16th duke was his kinsman Edward Hamilton Seymour (1860–1931). His grandson Percy Hamilton Seymour (1910–   ) is the 18th duke.

SOMERSET, EDMUND BEAUFORT, Duke of (c. 1406–1455), leader of the Lancastrians on the outbreak of the Wars of the Roses (*q.v.*), the most notable of the second generation of the Beaufort (*q.v.*) family, was the son of John, earl of Somerset. His early career was military: a prisoner in France (1421–1427), on Cardinal Beaufort's Bohemian crusade (1429), and again in the French wars in the 1430s; he was created a Knight of the Garter (1436), earl of Dorset (1442), and marquess of Dorset (1443). In 1447 he was appointed captain general in France and Guienne; in 1448 he was made duke of Somerset and in the following years he presided over the loss of English conquests in northern France.

Although the Beauforts had been barred from the succession (1407) by Henry IV, Somerset was, nevertheless, after the king the senior surviving male member of the House of Lancaster. With the death (1450) of William de la Pole, duke of Suffolk, he was the natural leader of the old court faction against the new opposition of Richard, duke of York. Through his handling of the king he did not do badly in the confused years 1450–55, during which the first sides were taken for the conflict. He survived an appeal (1450–51), was committed to the Tower (*c.* December 1453) during the king's first imbecility, and emerged early in 1455 with the king's returning sanity. York seems to have determined to redress the political balance by force of arms; and at the first Battle of St. Albans on May 22, 1455, Somerset was sought out and killed.

SOMERSET, EDWARD SEYMOUR, 1st Duke of (c. 1500–1552), was protector of England in the reign of Edward VI. Born about 1500, he was the eldest surviving son of Sir John Seymour (d. 1536) of Wolf hall, Wiltshire. The Seymours claimed descent from a companion of William the Conqueror, who took his name from St. Maur-sur-Loire in Touraine; and the protector's mother was descended from Edward III. Edward was page of honour to Mary Tudor at her marriage with Louis XII in 1514, served in the duke of Suffolk's campaign in France in 1523 and accompanied Cardinal Wolsey on his embassy to France in 1527. Henry VIII, to whom he became (1530) squire of the body, married his sister Jane in 1536, and Edward was created Viscount Beauchamp, and, after the birth of Edward VI, earl of Hertford.

In 1541, during Henry's absence in the north, Hertford, Thomas Cranmer and Baron Audley had the chief management of affairs in London; in Sept. 1542 Hertford was appointed warden of the Scottish marches, and in December lord high admiral, a post which he almost immediately relinquished in favour of John Dudley, Viscount Lisle, later earl of Warwick and duke of Northumberland (*q.v.*). In Feb. 1544 Hertford was made lieutenant general in the north and instructed to punish the Scots for their repudiation of the treaty of marriage between Prince Edward and the infant Mary Queen of Scots. He landed at Leith in May, captured and pillaged Edinburgh, and returned a month later. He then served at Boulogne, returning to Scotland in Sept. 1545 to avenge the Scottish victory at Ancrum moor. In March 1546 he was sent to Boulogne to supersede Henry Howard, earl of Surrey (*q.v.*); and from October to the end of Henry's reign he was in attendance on the king, engaged in that unrecorded struggle for predominance which was to determine the complexion of the government during the coming minority. Personal, political and religious rivalry separated him and Lisle from the Howards, and Surrey's attempt to secure the predominance of his family led to his own execution and his father's imprisonment.

Their overthrow had barely been accomplished when Henry VIII died. He had had no statutory power to appoint a protector, but, in the council of regency which he nominated, Hertford and Lisle enjoyed a decisive preponderance; and the council deter-

mined to follow precedent and appoint a protector. They chose Hertford (now duke of Somerset), and he quickly emancipated himself from the trammels originally imposed on him; he was king in everything but name. He used his authority to divest the government of the apparatus of absolutism perfected by Thomas Cromwell. In his first parliament, which met in Nov. 1547, he procured the repeal of all the heresy laws and nearly all the treason laws passed since Edward III. In foreign affairs, also, he at first adopted a more liberal policy. He had protested against his instruction in 1544, and now dropped the claim to suzerainty over Scotland which Henry VIII had revived. He sought to win over the Scots by promises of autonomy, free trade and equal privileges with England. But Scottish sentiment, backed by Roman Catholic influence and by French intrigues, money and men, proved too strong for Somerset's amiable invitations. The Scots turned a deaf ear to his persuasions; the protector led another army into Scotland in Sept. 1547 and won the battle of Pinkie (Sept. 10).

Somerset apparently thought that the religious question could be settled by public discussion and throughout 1547 and 1548 England went as it pleased so far as church services were concerned. All sorts of experiments were tried and the country was involved in a grand theological debate, in which Protestant refugees from abroad hastened to join. The result convinced the protector that the government must prescribe one uniform order which all should be persuaded or constrained to obey; but the first Book of Common Prayer, which was imposed by the first Act of Uniformity in 1549, was a studious compromise between the new and the old learning, very different from the Protestantism of the second book imposed in 1552 after Somerset had been removed. The Catholic risings in the west in 1549 added to Somerset's difficulties, but were not the cause of his fall. The factious and treasonable conduct of his brother Thomas Seymour (*q.v.*), lord high admiral, in whose execution (March 20, 1549) he weakly acquiesced, also impaired his authority. But the main cause of his ruin was the divergence between him and the majority of the council over the questions of constitutional liberty and enclosures of the commons. His efforts to check enclosures were foiled, and the popular revolts which resulted from their failure weakened his position. He was divided in mind between his sympathy with the rebels and his duty to maintain law and order. France seized the opportunity to declare war on Aug. 8; and the outlying forts in the Boulonnais fell into their hands, while the Scots captured Haddington.

These misfortunes gave a handle to Somerset's enemies. Warwick combined on the same temporary platform Catholics who resented the Book of Common Prayer, Protestants who thought Somerset's mildness paltering with God's truth and the wealthy classes as a whole. In September he concerted measures with the former lord chancellor Wriothesley; and in October, after a vain effort to rouse the masses in his favour, Somerset was deprived of the protectorate and sent to the Tower. But the hostile coalition broke up as soon as it had to frame a constructive policy. Warwick jockeyed the Catholics out of the council and prepared to advance along Protestant lines. He could hardly combine proscription of the Catholics with that of Somerset, and the duke was released in Feb. 1550. For a time the rivals seemed to agree, and Warwick's son married Somerset's daughter. But growing discontent with Warwick made Somerset too dangerous. In Oct. 1551, after Warwick had been created duke of Northumberland, Somerset was sent to the Tower on an exaggerated charge of treason, which broke down at his trial. He was, however, as a sort of compromise, condemned on a charge of felony for having sought to effect a change of government. Few expected that the sentence would be carried out, and apparently Northumberland found it necessary to forge an instruction from Edward VI to that effect. Somerset was executed on Jan. 22, 1552.

See A. F. Pollard, *England Under Protector Somerset* (1900), also his article in the *Dictionary of National Biography* and vol. vi of *Political History of England* (1910). (A. F. Po.; R. B. Wm.)

SOMERSET, ROBERT CARR (or Ker), Earl of (*c.* 1590–1645), Scottish politician who stood high in the favour of King James I. He was the youngest son of Sir Thomas Ker of Ferniehurst by his second wife, Janet, sister of Sir Walter Scott of Buccleuch, and may have accompanied James as page to England, but his early history is obscure. In December 1607 he was knighted and made a gentleman of the bedchamber and thereafter rose rapidly in royal favour. Entirely devoid of all high intellectual qualities, Carr was endowed with good looks, excellent spirits, and considerable personal accomplishments. These advantages were sufficient for James. In 1609 the king conferred on Carr Sir Walter Ralegh's forfeited manor of Sherborne. Carr's influence was already such that in 1610–11 he persuaded the king to dissolve his first parliament, which had shown signs of attacking the Scottish favourites. On March 25, 1611, he was created Viscount Rochester, and subsequently a privy councilor (April 1612), and on Lord Salisbury's death in 1612 he began in July to act as the king's secretary. On Nov. 3, 1613, he was advanced to the earldom of Somerset, in December was appointed treasurer of Scotland, and in 1614 lord chamberlain. Somerset fell from favour in 1615, when the circumstances of the murder of Sir Thomas Overbury in 1613 were disclosed, and he and his wife, who had secured a divorce from the earl of Essex to marry him, were implicated. For this story *see* Overbury, Sir Thomas. Possibly Somerset was no more than an accessory after the event. He was pardoned in 1624, and from that time disappears from history. He died in July 1645.

See the article by S. R. Gardiner in the *Dictionary of National Biography*, with authorities there cited; G. E. Cokayne, *Complete Peerage*, xii (1953). (R. B. Wm.)

SOMERSET, a southwestern county of England, bounded north by the Bristol Channel, the Avon River, and Gloucestershire, east by Wiltshire, south and west by Dorset and Devon. The area of the geographical county is 1,614 sq.mi. (4,179 sq.km.).

Physical Geography.—The county consists of a basin surrounded on three sides by hills and limited on the fourth by the sea. The northern hills are the Mendips, composed of Carboniferous Limestone, stretching from Nunney to the sea and appearing again in the islands of Steep Holme and Flat Holme, which link the structure of Somerset with that of South Wales (*see* also Mendip Hills). The summit of the Mendips is a long tableland between 500 and 1,000 ft. (150 and 300 m.) in height, but rising in the west to just over the latter figure. To the north they die away gently, as a number of low hills, toward the Avon. There the Limestone is covered in places by Coal Measures, but most of the rocks are Triassic. Southward the Mendip Hills drop steeply in an abrupt line broken by many coombs; *e.g.*, the gorge of Cheddar. The basin to the south is composed mainly of Triassic rocks, which, near the sea and along the valleys, are covered by recent alluvium. The basin is usually lower in its western than in its eastern part, which is known generally as Sedgemoor. The large basin is subdivided into those of the Parrett and the Brue by the Polden Hills, which run parallel to the Mendips from Butleigh to Puriton. To the west of the Parrett rise the Quantock Hills, which are outliers of the Devonian moorlands of Exmoor and the Brendon Hills. These three hill groups consist almost entirely of Devonian rocks, and their highest points respectively are Will's Neck (1,261 ft.; 384 m.), Dunkery Beacon (1,706 ft.; 520 m.), and Lype Hill (1,391 ft.; 424 m.). Exmoor (*q.v.*) forest covers the western extremity of Somerset and a large tract of Devon adjoining it. From Crewkerne along the southern and eastern borders of the county as far as the Avon runs a more or less continuous line of low Jurassic hills, while around Chard in the south there is a fair extent of Cretaceous rocks.

The climate of Somerset is mild and equable except on the high ground of the western hills and Mendips. The annual rainfall averages 34 in. (864 mm.) but there is a wide variation within the county from over 72 in. (1,829 mm.) on Exmoor to 25 in. (635 mm.) in the Taunton-Langport area.

The diversity of the geological formations in Somerset gives the county an unusual variety of landscape with dramatic changes of scenery; it also gives rise to a corresponding variety of soil fertility and agricultural pattern, from the market garden areas near South Petherton, Bridgwater, and Cheddar to the rough grazings of the highlands of Exmoor and the Quantocks.

The flat alluvial levels and peat moors of central Somerset support few trees but over 1,000 ac. (405 ha.) produce withies for the manufacture of baskets. The rest of the county is well wooded and the majority of the woodlands are small and scattered and predominantly composed of the hardwoods oak, ash, and beech. The Forestry Commission owns a total of 12,738 ac. (5,155 ha.) in Somerset (1963) and approximately 44,000 ac. (18,000 ha.) are privately owned. There is an increasing interest in the county's woodland which is attracting new investment to finance the replanting of woods.

Considerable areas of Somerset are only sparsely inhabited and wildlife flourishes. Wild red deer are still found on Exmoor and the Quantocks; also a peculiar breed of ponies, hardy and small. Badgers and otters are not uncommon in many areas. Stag and fox hunting is popular. There is a limited amount of sea fishing in the Bristol Channel and salmon and trout are taken in the rivers and reservoirs. Steep Holme, an island opposite Weston-super-Mare, is a nature reserve and bird sanctuary where the wild peony is well established. Sharpham Moor and Stert Island are also nature reserves and long stretches of the coast in Bridgwater Bay are protected areas for birds. Exmoor is a national park (created 1954), and the Quantocks were designated an area of outstanding natural beauty in 1956. The National Trust owned 16,074 ac. (6,505 ha.) and protected 41 ac. (17 ha.) in 1963.

History.—In early postglacial times the lowlands were morasses and the claylands forested, and so man, when he came to the district, settled on the open heights—the less fertile old rocks of the west, the chalk of the south, the limestone of the Mendips and the oolites on the east—and the caves of Mendip have yielded valuable evidence of early prehistoric cultures. In the Mendips are the Cheddar caves and Wookey Hole. Investigations have indicated the existence of Mesolithic sites on the moors and in the western hills. Excavations of tumuli and hilltop earthworks have produced evidence of occupation during the Bronze and early Iron ages, but the most remarkable settlement of the pre-Roman period was that of the lake-village at Glastonbury (*q.v.*).

The Romans overran Somerset after the Claudian conquest of A.D. 43, and remains of the period of the Roman occupation are numerous, particularly between the Parrett and the Avon. Bath (Aquae Sulis), which was probably a settlement in earlier times, became, on account of the medicinal properties of its waters, an important Roman centre where the Fosse Way from Cirencester met another road from Silchester. The Fosse Way was continued from Bath to near Seaton, Devon, and on it was a station at Ilchester (Lindinae) where it crossed the Yeo. Remains of about 50 Roman villas or related structures were discovered in the county. Charterhouse in the Mendips was a centre of the Roman lead mining industry. In the 6th century Somerset was the debatable borderland between the Welsh and Saxons, the latter of whom pushed their way slowly westward. By 658 it had been conquered by the West Saxons as far as the Parrett, and there followed a struggle between the kingdoms of Wessex and Mercia, which led to the organization of the lands east of the Parrett as part of the kingdom of Wessex. About this time the monastery of Glastonbury was restored by Ine who completed the conquest of west Somerset. In the 7th century Somerset, as part of the kingdom of Wessex, was included in the diocese of Winchester. The new bishopric of Sherborne, founded in 705, contained the county until 909, when the see was divided into the dioceses of Salisbury, Exeter, and Wells, the latter including the whole of Somerset. The diocese was divided into three archdeaconries. Disputes later between the chapters of Bath and Wells as to the election of the bishop led to a compromise in 1245, the election being by the chapters jointly, and the see being known as the bishopric of Bath and Wells.

King Alfred's victory in 878, followed by the Peace of Wedmore, ended the incursions of the Danes for a time, but 100 years later they were again a great danger and made frequent raids on the west coast of Somerset. At the Conquest Somerset was divided into about 700 fiefs, held almost entirely by the Normans; the king's lands were of great extent and importance and the bishop of Winchester owned a vast property of which Taunton was the centre. In the 11th century or a little later many Norman castles were built, some of which have survived (*e.g.*, Dunster, Taunton).

The chief families of the county in the Middle Ages were those of De Mohun, Malet, Revel, De Courci, Montacute, Beauchamp and Beaufort, who bore the titles of earls or dukes of Somerset from 1397 to 1472. Edward Seymour was made duke of Somerset in 1547, and in 1660 the title was restored to the Seymour family by whom it was still held in modern times. The marquess of Bath is the male representative of the Thynne family, which has long been settled in the county.

Somerset was too distant and isolated to take much share in the early baronial rebellions or in the Wars of the Roses, and was really without political history until the end of the Middle Ages. In 1547 and 1549 there were rebellions against enclosures. Somerset took a considerable part in the Civil War, and with the exception of Taunton was Royalist, the strongholds being garrisoned and held for the king, but they all fell in 1645, and the county was subdued by the Parliamentary forces. It was the theatre of Monmouth's Rebellion, and he was proclaimed king at Taunton in 1685. The Battle of Sedgemoor on July 6 was followed in the autumn by the "bloody assizes" held by Judge George Jeffreys, in Taunton Castle and at Wells.

Examples of medieval ecclesiastical architecture include the Cathedral Church of Wells, Bath Abbey, and the ruins of Glastonbury Abbey, but Somerset's greatest wealth lies in its parish churches. Of these some have Norman and Early English features, but the most interesting, especially for their magnificent towers, are those in the Perpendicular style, of which the outstanding examples are at Taunton, Glastonbury, Huish Episcopi, Leigh upon Mendip, and Kingsbury. Dunster Castle, which dates from 1070, has been in the Luttrell family since 1376. Fine examples of domestic architecture of the medieval and Tudor periods are at Lytes Cary, Meare, Martock, Montacute, Barrington, and Brympton; the imposing 18th-century architecture of Bath found echoes in simpler work in other towns in the county.

The county was represented in the parliament of 1290; in 1295 it was represented by two knights, and 12 boroughs returned two burgesses each. It continued to return two members until 1832, when it was divided into Somerset East and Somerset West, each division returning two members. Two additional members were returned after 1867 for a third (the Mid-Somerset) division until by the act of 1885 the whole county was divided into seven.

Population and Administration.—The administrative area of the county is 1,603.7 sq.mi. (4,152 sq.km.). Taunton (pop. [1961] 35,192) is the county town and a municipal borough. Bath (80,901) is a city and county borough. The other municipal boroughs are Bridgwater (25,600), Chard (5,779), Wells (6,715), Weston-super-Mare (43,938), and Yeovil (24,598). There are 13 urban and 16 rural districts. The county is in the western circuit, assizes are held at Taunton and Wells, and it has one court of quarter sessions. The boroughs of Bath and Bridgwater have separate courts of quarter sessions. Somerset is in the diocese of Bath and Wells, excepting small parts in the diocese of Bristol.

Besides the county borough of Bath, there are six parliamentary divisions, each returning one member; the county includes part of the parliamentary borough of Bristol.

The Economy.—The main industry is agriculture. Other industries centre on consumer goods in food and drink, clothing, textiles, boots and shoes, paper and printing, furniture and woodworking, but there are no great concentrations of industry. The years of World War II strengthened the engineering and metal-using industries in the southeastern part of the county and new industries including the manufacture of chemicals and scientific instruments were introduced.

Somerset is the leading dairying county of England. Permanent grassland predominates, especially on the lower grounds, but there are areas where arable farming reaches a very high standard. Market gardening and fruit growing flourish in certain favourable districts. Cider making has been practised for centuries, and Cheddar has given its name to a famous cheese. Stock raising is mainly concentrated on the western hills, Exmoor, the Brendons, and Quantocks being known for their calves raised for beef. Sheep

breeding is similarly concentrated mainly in the west.

The chief mineral product is limestone from the Mendips. Peat is found in the Glastonbury area, clay for tiles and brickmaking near Bridgwater, and fuller's earth near Bath. There is coal mining in the Radstock area.

Traditional manufactures include gloves at Yeovil and Wincanton, lace at Chard, linen at Crewkerne, silk at Taunton and Shepton Mallet, and serge at Wellington. A new development in a remote rural setting was the construction (1957–65) of a nuclear power station at Hinkley Point, about 10 mi. (16 km.) NW of Bridgwater on the north coast of Somerset.

The holiday and tourist industry is economically important not only at the seaside towns such as Weston-super-Mare, Burnham-on-Sea and Minehead, but also inland at Taunton, Wells, Cheddar, on the Quantocks, and on Exmoor.

Somerset is served by the Western region of British railways. There is direct connection with London (Paddington) via Westbury and Reading, with the Midlands and the north via Bristol; and with the west. An air service between Weston-super-Mare and Cardiff supplements the summer steamship services. Harbours on the lower Parrett include those at Combwich for supplies for the nuclear power station at Hinkley Point and at Dunball for petroleum from South Wales refineries. At Watchet, coal and raw materials for the paper mills are imported.

SOMERVILE, WILLIAM (1675–1742), English author best known for his poems on hunting, was born Sept. 2, 1675, at Colwich, Staffordshire. He was educated first at Winchester, whence he proceeded in 1694 to New College, Oxford, where he was a fellow. He was admitted at the Middle Temple, but retained his New College fellowship until 1705, when upon his father's death he resigned it and settled at Edstone, near Henley-in-Arden, Warwickshire. He remained there until his death on July 17, 1742.

Somervile lived the life of a country gentleman, serving with praise as justice, and indulging in the field sports that were to make up the subject matter of his best-known poems. His best-known work, *The Chase* (1735), traces the history of hunting up to the Norman Conquest, and instructs on kennel design, hare hunting, stag hunting, the breeding and training of puppies, dog diseases and bites, with frequent digressions including one on Oriental hunting. *The Chase* went through 11 editions in the 18th century; the 1796 edition with a critical essay by John Aikin was illustrated by Thomas Bewick. *Field Sports* (1742), on hawking, supplements *The Chase*. He also published *The Two Springs* (1725), a fable; *Occasional Poems, Translations, Fables, Tales* (1727), which include appreciations of Pope and Addison and some lines to James Thomson with whose *The Seasons* his *The Chase* has some affinities; and *Hobbinol, or the Rural Games* (1740), a burlesque of rustic May games at Evesham. Somervile enjoyed popularity with literate sportsmen into the 19th century and was included in Samuel Johnson's *Lives of the Poets* (1781).

See A. H. Higginson (ed.), *The Chase* (1929).

SOMERVILLE, a city of Middlesex County, Mass., U.S., on the Mystic River, is surrounded by Boston (Charlestown), Cambridge, Arlington, and Medford. The last of the Mystic Valley towns to separate from the early Charlestown colony, it was originally known as the Cow Commons and was entirely fenced in until 1685. In the city stands the Old Powder House, from which British Gen. Thomas Gage seized 250 half-barrels of gunpowder in 1774. In 1775 it became the magazine of the American forces besieging Boston. After the American Revolution brickmaking grew to be an important industry, and the opening of the Middlesex Canal (1803) which passed through Somerville added to its desirability as an industrial site. It was incorporated as a town in 1842 and became a city in 1871.

The greatest growth in population and industrial activity occurred after 1900, when slaughtering and packing became the principal industries. By mid-20th century Somerville had become a working and middle-class residential suburb of Boston with substantial industrial development and importance as a distribution centre. Pop. (1960) 94,697; for comparative population figures *see* table in MASSACHUSETTS: *Population*. (L. G. BA.)

SOMERVILLE, a borough of north-central New Jersey, U.S., on the Raritan River, is located 36 mi. SW of New York City; the seat of Somerset County. It is a retail-trade centre for a large area of farms, manufacturing plants and housing developments. First settled in the late 17th century by farmers, it became the county seat when the county was established in 1783. It was incorporated as a town in 1863 and as a borough in 1909. In the 1750s the Rev. John Frelinghuysen founded the first seminary of the Dutch Reformed Church in America. From these humble origins came Queens College, chartered in 1766 and now Rutgers—the State University (*see* NEW JERSEY: *Education*), and the New Brunswick Theological seminary. The Old Dutch parsonage, where Frelinghuysen lived, is open to the public, as is the Wallace House, used as headquarters by George Washington while his troops were quartered at Camp Middlebrook. The Duke estate, established in 1893 by James B. Duke, the tobacco magnate, is a research and exhibition centre for the New York Horticultural Society. For comparative population figures *see* table in NEW JERSEY: *Population*. (E. R. D.)

SOMERVILLE AND ROSS: *see* MARTIN, VIOLET FLORENCE.

SOMME, a *département* of northern France, formed in 1790 from a large part of the province of Picardy, including the districts of Ponthieu, Vimeu, Amiénois, Santerre, and Vermandois, and also from a neighbouring small portion of Artois. It is bounded north by the *département* of Pas-de-Calais, east by Aisne, south by Oise, and southwest by Seine-Maritime. To the west it fronts the English Channel for about 30 mi. (48 km.). Area, 2,384 sq.mi. (6,175 sq.km.). Pop. (1962) 488,225.

The *département* consists largely of tracts of hedgeless, arable land, typical of the rolling chalk country that occupies the northern part of the Paris Basin. The flat, alluvial-floored trench occupied by the Somme River (*q.v.*) is the largest of the valleys, aligned southeast-northwest, that groove these dry chalk plateaus. It forms the axis of the *département*, which stretches north to the Authie River and southwest to the Bresle River. The Somme, in its marshy valley, forms a historic line of defense across the approach to Paris from the Low Countries, and the *département* was the scene of long and heavy fighting during World War I. Many war cemeteries in the countryside mark its battlefields.

Much of the chalk upland is covered with limon, rendering it very fertile. Sugar beet is especially a crop of the limon soil, cultivated in association with wheat. Wheat is everywhere the pivot of the crop rotations, supported by other cereal and fodder crops. Some chicory, tobacco, and flax are grown, but the *département* lies wholly north of the limit of viticulture. In the coastal districts there is more pasture for grazing, but the arable farms everywhere carry a high density of stall-fed cattle. Fallows have been replaced by rotation crops and sheep have therefore greatly diminished in number.

The longshore drift sweeps sediment against the coast as it trends north from Le Tréport, and the Somme estuary suffers from severe silting. Between the estuaries the chalk cliffs of the former coastline are now separated from the sea by a strip of marshland behind the piled up sand dunes. This marshland, now drained by dikes and converted into market gardens and meadows, is the Bas Champs of Marquenterre. Market gardens also occupy the peaty floors of the river valleys. These are areas of small holdings, but on the chalk upland holdings of medium size prevail and are farmed by their owners. The farms, typically consisting of a substantial group of buildings surrounding an open courtyard, are clustered in villages. Rural handicrafts, once widely practised,

included locksmithery in Vimeu and hosiery in Santerre. These handicrafts have declined since the early 19th century. In the market towns textile industries have survived, especially at Amiens, which manufactures velours and heavy woolens. There are also engineering works, sugar refineries, breweries, distilleries, and flourmills.

Amiens (*q.v.*), the ancient capital of Picardy (*q.v.*), situated at the main crossing of the Somme valley, has become the chief focus of rail and road routes. It is the largest town and the *préfecture* of the *département*, which is divided into four *arrondissements*, centred upon Amiens, Abbeville, Montdidier, and Péronne. Abbeville, at the head of the Somme estuary, with the lowest bridge, is another important route centre. Poix, Roye, Ham, Albert, and Doullens are the other market towns. The *département* forms the diocese of Amiens, whose great Gothic cathedral of Notre Dame is the largest in France. Amiens also has the court of appeal, but the *département* comes under the *académie* at Lille for the administration of education. Few old buildings survived the devastation of two world wars, and the towns have been largely rebuilt. (Ar. E. S.)

SOMME RIVER, in northern France, 152 mi. (245 km.) long, flows northwestward to the English Channel across the *département* of Somme to which it gives its name, and the ancient province of Picardy. Its headstreams, including the Avre, from the rich arable country of Vermandois and Santerre, converge upon Amiens, whence the Somme follows a braided course along the flat floor of a trench cut across the chalk country. Its valley, floored with alluvium, is a marshy belt, and its line has been an important barrier in the approach from Flanders toward Paris, and as such has been of great strategic importance. The upper basin of the Somme was the scene of heavy fighting during World War I. The valley, which has been extensively reclaimed, is now occupied by meadows and market gardens (*hortillonnages*) served by a network of drainage canals; the flanking chalk uplands, with *limon* soils, are the domain of wheat and sugar beet. Below its lowest bridge, at Abbeville, the Somme enters a sand-encumbered estuary, with the little port of Saint-Valery at its mouth. The river has been canalized, and from the upper valley there are canals to the Oise (Canal de Somme) and the Escaut or Scheldt (Canal de Saint-Quentin) connecting it with the navigable waterways that link Paris and Flanders. (Ar. E. S.)

SOMNAMBULISM: *see* Hypnosis; Hysteria.

SOMNATH (Patan Somnath, Somnatha-Patan), an ancient ruined city on the southern coast of Gujarat, India, 110 mi. (177 km.) S of Rajkot. It is the site of the famous temple of Siva as Somanatha, "lord of the soma," a sacred intoxicating plant, and, by extension, "lord of the moon." The temple was sacked and its linga or phallic emblem broken into pieces by Mahmud of Ghazni in A.D. 1024–25. Reconstructed for the second time in 1169, the temple was destroyed in the final Muslim invasions of the late 13th century. It was subsequently rebuilt and destroyed on several occasions; the last reconstruction was begun in 1951. According to an ancient tradition in the Mahabharata Somnath was the scene of the internecine massacre of the Yadava clan and of the subsequent death of Krishna (*q.v.*). Recent excavations there have revealed a settlement going back to *c.* 1500 B.C. Patan (pop. [1961] 13,927), a port on the old city site, is now overshadowed by the adjacent port of Veraval (pop. [1961] 46,637).

(F. R. A.)

SON, a river of northeastern central India, 487 mi. (784 km.) long, flowing in general east-northeast. It is the chief tributary received by the Ganges from the south. Although the valley of the Son is almost a continuation of that of the Narmada (Narbada) and geologists refer to the "Narmada-Son trough," unlike the Narmada it does not serve as a main line of communication. The valley is largely forested—especially with sal (*Shorea*)—and sparsely populated, and has only occasional small patches of cultivation. To the north of the valley is the Kaimur Range; on the south the river collects the drainage of the northern parts of the Chota Nagpur Plateau. There rainfall is restricted to the rainy season (June–September); for much of the year the Son carries little water. The river cuts through the eastern end of the Kaimur Range to flow northeastward across the plain to enter the Ganges 10 mi. above Patna. An outcrop of limestone has permitted the development of a cement works with coal from Daltonganj. Dams have been constructed on some of the tributaries and where the river disgorges onto the plain is the important weir at Dehri, from which 600,000 ac. (240,000 ha.) are irrigated. (L. D. S.)

SONATA, in music (Italian, "sounded," *i.e.*, by instruments as opposed to *cantata*, "sung"), a term first used to describe a specific instrumental work by Giacomo Gorzanis, who, in his lute book of 1561, applied it to a suite of dances. At the beginning of the 17th century the term was associated with an instrumental composition, closely allied to the fantasia (*q.v.*). Loosely fugal in texture, and sometimes with brief sections in contrasting tempos or rhythms, it was an instrumental counterpart to the contemporary madrigal. An example of this form is Giovanni Gabrieli's *Canzoni et sonate . . . per sonare con ogni sorte de instrumenti* ("to be played on all kinds of instruments"), published in Venice, 1615.

Subsequent uses of the term sonata have varied so greatly that the different forms covered by the term must be dealt with separately. It has been customary, however, to confine the term to small groups of instruments playing not more than one to a part; and to regard as sonatas only those works in more than one movement—though the latter qualification does not always hold good for works of earlier periods (*e.g.*, Scarlatti's sonatas for harpsichord; *see* below, *The Transition to True Sonata Form*).

THE BAROQUE SONATA

In Italy at the beginning of the 17th century the fantasia developed a tendency to be built up in brief sections, and it was these sections which were made slightly longer and more distinct to form sonatas of several movements. Some of these sonata movements continued to be given the loosely fugal texture characteristic of the fantasia; others were in the form of dances such as the saraband or the coranto (*see* also Dance Forms in Music). Such dances were familiar in the court balls and other fashionable entertainments of the period, to which the newly developed family of violins was regarded as a particularly suitable accompaniment because of their brilliant tone and assertive articulation. The sonata, like the violin family itself, was first cultivated by the Italian musicians, and developments both of the form and of the instruments were interdependent.

The old equal-voiced polyphony of the 16th-century fantasia continued to be developed by English composers of the early 17th century, whose idiom was thoroughly instrumental, into a magnificent school of contrapuntal chamber music for viols (a family of instruments whose lighter tone and more transparent colouring enable them to perform their own elaborate counterpoint with impressive clarity). Elsewhere—and above all in Italy—the trend in music passed from equal-voiced polyphony in the direction of solo melody, to which the viols were less suited than the violins. Here is one of the distinguishing characteristics of the sonata as opposed to the fantasia. Although the texture of the Baroque sonata remained essentially contrapuntal, and although some of its movements (especially the second) tended to be fugal, there is no equal-voice polyphony in the 16th-century sense; the emphasis is on solo melody.

This solo melody is ordinarily supported by a bass line which is almost, if not quite, as melodic in quality as the main melody itself. A further development greatly favoured as the 17th century progressed consisted in writing two main melodies at about the same level of pitch; these continually cross and recross in the treble register until it is hard to say which, if either, takes primacy. It is as if the solo melody had divided into a pair of copartners still supported at some distance below by the strongly melodic bass line. The harmony in between is not filled out with independent parts as it is in the fantasia, that is to say built up out of equal-voiced polyphony. On the contrary, it is left to the continuo player to improvise upon the bass line, which, with a few figures to inform him of the harmony, is all that the composer will normally have given him to work upon (*see* Thorough Bass). There could be no clearer indication of the new inclination to ex-

ploit melody at the expense of equal-voiced polyphony.

These dual-melody sonatas became known as trio sonatas. Two treble melodies and one bass melody add up to three; and though a keyboard, lute, or other continuo accompaniment was also normally used, the work was regarded as complete without this fourth instrument. The music can be performed without continuo, though this leaves it less rich and brilliant. When a continuo instrument was used, it was possible to dispense with a melody instrument playing the bass, but this, too, was felt to be an undesirable impoverishment. Solo sonatas for violin or other instruments were also developed through the 17th century, but the trio sonata became the standard form of serious chamber music, and held a position corresponding to that of the string quartet from the time of Haydn onward. Keyboard sonatas appeared intermittently in the 17th century, notably those of Johann Kunhau (1660–1722).

The sonata as understood in the Baroque period owes most to the famous violinist-composers of the Italian school. These were successfully active very early in the 17th century, but the school reached a peak in the solo and trio sonatas of Arcangelo Corelli (1653–1713). In the same generation, Henry Purcell (1659–95), who had already composed the last great English fantasias, became acquainted with the Italian idiom, and produced the first English sonatas of enduring significance. These, for two violins and continuo and for three violins and continuo, have not the classic perfection of form of the Corelli sonatas; but the harmonic interest is greater in Purcell's music, and the feeling is warmer and more heart-searching. These features are partly due to Purcell's individual genius, and partly to the singular intensity of the English musical tradition which he inherited.

The Italian sonata as perfected by Corelli took two slightly different forms: one designed for musical performance in church; the other for secular occasions. The former variety was the *sonata da chiesa* ("church sonata"), the latter the *sonata de camera* ("chamber sonata"). Dance movements were favoured in chamber sonatas, but not in church sonatas, the style of which might be a little more solemn; in other respects there is no difference which strikes the modern ear.

A further distinction greatly stressed at the time, but which has become less noticeable to modern ears, is that between the Italian and French styles. This distinction provoked much controversy in the second half of the 17th century and most of the 18th. The Italian style brought the melody into prominence and employed rich harmonies characterized by suspensions. A flowing tempo was frequently desirable, the parts were often to be quiet-moving and the movements, normally without a descriptive title, were designed to follow each other in an established order. The French instrumental style was notable for precise, clearly marked rhythms, short phrases, and, in the slow movements, elegant ornamentation and poignant sentiment. The movements, often with literary or pictorial associations, were assembled in many different ways. The Italian style was regarded as brilliant by its admirers, but as intemperate by its detractors; the French style was regarded as tenderly expressive by its admirers, but as stiff and insipid by its detractors. The genius of François Couperin (1668–1733) rose above this embittered quarrel; he not only composed in both national styles, but combined them in a series of splendid trio sonatas which are to the French tradition what Purcell's are to the English.

The Germans were early followers of the Italians and produced solo violin sonatas and trio sonatas during the 17th century, as well as sonatas in which the viola da gamba takes a middle part. G. P. Telemann (1681–1767), G. F. Handel (1685–1759), and others composed many sonatas of value. The greatest Baroque sonatas come from J. S. Bach, particularly those for unaccompanied violin (for which there are German precedents) or violoncello, and for violin with harpsichord obbligato or viola da gamba with harpsichord obbligato; he also wrote a small number of trio sonatas. His writing for the violin owed something to Antonio Vivaldi, the greatest of all the 18th-century Italian violinist-composers, whom he greatly admired.

Though these Baroque works were called sonatas, and are still rightly known by this name, they can be more accurately described as suites rather than as sonatas in the later sense of the term. Moreover, there is no essential difference between the Baroque sonata and the Baroque suite: they are basically the same form, for which other names, such as *partita* or *ordre*, were also freely in use.

The principle is to contrast a succession of movements each of which is more or less homogeneous in itself. The contrast may be of tempo, of rhythm, of major or minor mode, or of general style; an underlying unity is provided by retaining wholly or mainly the same key, occasionally varied by its near relatives. The degree of internal contrast within the movement varies, but it was never the determining element in the construction of the sonata, as it became from the time of Haydn onward.

The Transition to True Sonata Form.—The transition from the Baroque sonata, which is in effect a suite, to the classical sonata, which is in true sonata form, occupied the middle of the 18th century. An outstanding pioneer was Domenico Scarlatti (1685–1757). His father, Alessandro, was in the front rank of Italian opera composers in his day; the son, Domenico, was in advance of his. Though born in the same year as Handel and J. S. Bach, Domenico Scarlatti did much to prepare the change of style that was to follow those two last geniuses of the Baroque period. Most of his sonatas for harpsichord are untypical in one respect: they are essentially single-movement works, two of which, however, were frequently paired in performance. Within the single movement they make a deliberate and effective use of internal contrast, and it is this feature which became decisive in sonata form as understood from Haydn onward. Domenico Scarlatti combined astonishing brilliance with a remarkable depth of poetry, and his sonatas, though best classified as transitional from the formal viewpoint, are masterpieces in their own right.

J. S. Bach's sons continued the development away from the Baroque toward the subsequent conception of the sonata. In particular C. P. E. Bach (1714–88) and J. C. Bach (1735–82) contributed to the use of contrasted keys, not only between movements, but still more significantly within the movement. It is here that the history of true sonata form begins.

TRUE SONATA FORM

The term sonata form in its stricter modern use denotes both (1) the organization of tonal material within the movement and (2) the organization of the relationship between movements.

Material Within the Movement.—The main divisions within a movement in sonata form are: (1) the exposition; (2) the development; and (3) the recapitulation.

The Exposition.—The tonal material is not single, *i.e.*, of more or less uniform character (rhythm, tonality, etc.) as in a characteristic suite movement; it is dual, *i.e.*, it includes an inherent element of contrast. Its themes, though not necessarily two in number, present a conflict of mood which tends to divide the material into two fields of force. The inherent tension between these two fields is deliberately heightened by a conflict of key: the opening material is in the tonic or "home" key; the contrasting material is in a contrasting key, which, though normally in a close relationship to the "home" key, is sufficiently distinct to mark a certain distance from the starting point. The listener feels a sense of opposites: very often the familiar human opposition of a masculine with a feminine mood, or of an energetic with a reflective temperament, or of strength with tenderness. The establishment of this opposition is known as the exposition; it may have been preceded by an introduction. The exposition is commonly marked with repeat signs, but these are optional. Some expositions seem to gain from being heard twice, others not; the modern tendency is to omit the repeat.

The Development.—In the development, any portion of the material so far heard, and in many cases new, or seemingly new, material may appear in any order and in any combination. Frequently the material is broken down into its constituent fragments, and these fragments are themselves combined and developed. Opposing moods are illustrated and seen to interact. Tonality becomes as fluctuating as the argument. The key is in constant modulation; if it settles, it is likely to be in a tonality remote from either of

those established in the exposition. Toward the end of the development section a sense of premonition is introduced which is fulfilled by a return of the "home" key, and with it the original opening material.

The Recapitulation.—What now follows is the recapitulation. Both the opposites which set up their contrasting tonalities and their contrasting fields of force in the exposition are heard again and in the same order. They may show considerable differences on this second appearance; there may be felicitous new touches showing how little a second appearance need be mechanical; but the opposites are still recognizably and often literally the same. Their effect on the listener, however, is not the same. He hears them with new ears because he has lived through the revealing experience of the development. He is prepared, in consequence, to find their initial opposition reconciled, as opposing principles and people can become reconciled by being brought into relationship. This sense of inner reconciliation is confirmed, like the initial opposition, by the tonality. Instead of appearing in a key or keys contrasted with the "home" key, the opposing material now appears in the same, or mainly in the same, key as the opening material. What began as a conflict in the exposition proceeds as dialectic in the development and ends as synthesis in the recapitulation. The tension of the opposites is not so much relaxed as brought into balance. A coda may then follow, sometimes of such elaborate proportions as almost to amount to a further development; but whether this is so or not, a sonata-form movement is complete if, and only if, it ends with reconciliation.

A form is not a mold to be filled by a composer pouring suitable material into it; a vital form is based on the principle of organic growth. This principle is illustrated in many different ways. Mozart's sonata-form movements show different inclinations from Haydn's, and Beethoven's from Mozart's. But they all show the same principle based primarily on a conflict of mood and tonality which leads through development and interplay to reconciliation. It is a drama so fundamental to human experience that it may be readily seen why the expression of it in music produced a form of such enduring conviction. This reached its perfection in the three classical masters just mentioned, but it served some of the Romantics of the later 19th century equally well.

Relationship Between Movements.—The unified contrasts in the first aspect of sonata form (the organized exposition, development, and recapitulation of tonal material within the movement) continue into its second aspect (the organized relationship between the movements). The "sonata-form movement" as described above is the first movement of the sonata at its most characteristic: so much so that it is alternatively described as "first-movement form." This, however, is not a desirable alternative, since the first movement is not invariably in sonata form; and later movements quite often are. These normally comprise a slow movement in the middle, and a quick movement at the end, with the optional insertion of a lighter movement either before or after the slow movement. In the sonata as developed by Haydn the keys in which the separate movements are composed are contrasted with the same attention to dramatic effect as the key sequences within the movement.

This was not a new principle in music; but it was pressed to new lengths. Whereas a Baroque suite (even when passing under the name of a sonata) or indeed a late Baroque opera, with its suites of arias, is a series of arresting scenes, a sonata by Beethoven or an opera by Wagner is in the form of a dramatically developed plot. The dramatic element is greater in 19th-century music than in Baroque music; and the sonata is the chief instrumental form which gave strength and coherence to this new sense of drama.

While in the classical sonata there is not usually a conscious thematic connection between the material of one movement and another, some Romantic composers from Schumann onward experimented extensively in the use of transformed material. Liszt transformed his material in such a way that he was able to maintain the original elements of his themes throughout all movements of his sonata forms, but, though his poetic intentions were undeniable, his inspiration did not always sustain his preconceived plan. Deliberate use of the same material to fill out the different movements is alien to the spirit of sonata form, though fleeting references from one movement to another can add to the sense of coherence, and are often moving.

In sonata form, unity is achieved within a movement by relating the tonalities of the contrasting sections to an underlying key. The tonalities of the different movements are also related. The slow movement and the trio are normally contrasted in key with the other movements.

The slow movement does not usually follow the plan of the first-movement sonata form, since its slow-moving tempo would not allow an expanded development without unreasonably prolonging the length. A common form for the slow movement is the "aria" or *Lied* form, ABA, often called song form. This consists of: a section complete in itself; a section contrasting both in mood and tonality; and the first section repeated, often with substantial variation. An alternative, which can be as elaborate as the composer wishes, is variation form: a melody complete in itself; variations upon it; and, sometimes, the plain melody again. Some of Beethoven's slow movements are in variation form (*e.g.*, the piano sonatas op. 109 and op. 111; the string quartets op. 127 and op. 135).

The slow movement may be preceded or followed by a movement the purpose of which is to lighten the mood and relax the tension. In the 18th century the minuet was used for this purpose. This was often followed in suites and divertimentos by a second minuet (perhaps in the minor if the first was in the major), the first minuet then returning without its repeats. As the classical sonata developed, a "trio" became usual in place of the second minuet (the name probably deriving from the convention by which four-part writing was commonly replaced by three-part writing at this point). The convention was not obligatory and later declined. Many trios have an elegiac charm, almost a naïveté, providing relief in an otherwise tense composition. Later, the scherzo (*q.v.*) supplanted the minuet; the scherzo was sometimes followed by a trio, elements of which could be repeated. In all these schemes the function of this movement remains the same: to provide either light relief, or at least relief in the sense of some decisive change of mood (some of Beethoven's scherzos are notoriously ferocious).

The function of the last movement in a sonata is variable. Some works start with a first movement so powerful that the entire sequel becomes a prolonged commentary on it without detracting from its prominence. This is more commonly found in the works of Haydn or Mozart than in those of Beethoven. Another pattern is to set the main weight in the slow movement followed by a slighter but brilliant finale. It is also possible to lead up to a massive last movement to which the others seem no more than an elaborate preparation. A quiet and contemplative ending, again, can sometimes carry profound conviction. Rondo form and variation form are common choices; they are sometimes so handled (especially rondo form) as to contain elements of sonata form, while true sonata form (perhaps somewhat modified) is a further possibility for the last movement of a sonata, particularly if the first movement has been in some other form.

Symphonies, string quartets, and to some extent concertos of the 18th and 19th centuries are commonly, in effect, sonatas. At the beginning of the 20th century the concept which reached maturity with Haydn became transfigured by Sibelius, whose symphonies, though suffused with sonata principles, often grow from small germs, instead of developing self-sufficient material of contrasting elements ultimately reconciled.

The drama of key and modulation is at the basis of sonata form. If it is found to be of less value to 20th-century composers, this is not because they would not wish music to express such fundamental ideas as conflict, growth, and reconciliation, but because, tonality having lost much of its significance. other technical means must be found to express these perennial concepts.

SONDERBORG: *see* Aabenraa-Sonderborg.

SONDRIO, a town in Lombardy, Italy, and capital of Sondrio Province, lies in the Valtellina at an altitude of 1,017 ft. (310 m.) and on the Adda River, 82 mi. (132 km.) NE of Milan by rail. Pop. (1961) 19,455 (commune). Of interest are the archaeological museum and the Masegra castle (now barracks). The town, well known for its wines, is an agricultural and commercial centre, and has a cotton textile industry. It is connected by rail and road with Switzerland via Tirano and the Bernina Pass, and by road with the Stelvio Pass (9,052 ft. [2,759 m.]) and with Bolzano. Cableways link it with the winter-sports resorts of Madesimo, Bormio, Aprica, Caspoggio, Teglio, Chiesa in Val Malenco, Livigno, and Santa Caterina Valfurva.

SONDRIO PROVINCE, bounded north by Switzerland, comprises the Valtellina and the Liro and lower Mera valleys. Area 1,240 sq.mi. (3,212 sq.km.). Pop. (1961) 153,592. There are extensive vineyards and hydroelectric power is highly developed. (L. B.)

SON ET LUMIÈRE (SOUND AND LIGHT), a nighttime entertainment conceived by Paul Robert-Houdin, curator of the Château de Chambord on the Cosson River, France, where the first one was presented in 1952. Multicoloured lights of changing intensity are directed against the facade of a historic building or ruin. The changes of light are synchronized with a sound track (relayed through loudspeakers) carrying music and the dramatized story of the site. Usually no participants appear. Live effects such as smokebombs or fireworks are occasionally used for appropriate episodes.

The medium rapidly became popular in France, where by the middle 1960s about 50 annual productions took place, notably in the Loire Valley and also at Versailles and Les Invalides. Productions elsewhere on the European continent included Rome (the Forum) and Athens (the Parthenon), both in multilingual versions. The first British production was in 1957 (Greenwich Palace). Subsequent productions included Cardiff Castle, Portsmouth (H.M.S. "Victory"), Henley-on-Thames (Grey's Court), the Tower of London, Stirling Castle and the cathedrals at Gloucester and Norwich. The first presentation in the United States was given at Independence Hall, Philadelphia, Pa., in July 1962. The first African production took place at Cairo (the Giza pyramids) in April 1961; the first Asian production was at Delhi (the Red Fort) in March 1965. (A. A. BU.)

SONG, properly, a piece of music performed by a single voice, with or without instrumental accompaniment; songs for two or more voices are more accurately described as duets, trios, quartets, etc. The music of a song is normally a setting of intelligible words; examples of wordless songs (*vocalises*) occur in the works of 20th-century composers, but they are exceptional. Such a conception of song is possible only in a civilized society. To primitive man words and tune were inseparable, and this is largely true of European and American folk song. Primitive songs are also closely associated with nature and with the supernatural inherent in nature; hence they always have a definite purpose. In European and American folk songs purpose survives in the shape of lullabies, work songs, sea shanties, and the like; but a great many songs do no more than tell a story or sing of the joys and disappointments of love (*see* FOLK MUSIC).

Early European Song.—The records of European song, as distinct from folk song, are scanty before the 12th century. For recreation, monks and students sang songs in Latin, since this was the language of their education. The words of many of these have been preserved, but the tunes were rarely written down, either because they were well known or because the skill to record them was lacking, and possibly in some cases because the composers were anxious to preserve them for themselves. It is to the 12th-century troubadours (*q.v.*) in the south of France that we owe not only what appears to be a new art of lyrical poetry in the vernacular but also a large number of melodies wedded to the poems. This art was imitated by the *trouvères* (*q.v.*) in northern France, who have left a considerably larger corpus of songs with music, and also in Spain, Italy, and what is now Germany and Austria. Whether the melodies were written by the poets themselves or by musicians associated with them is a matter of dispute; but they are all highly organized, in most cases with an exact or modified repetition of the first section, and many of them reveal a subtlety of expression that has not been surpassed by any later composers. Songs of this kind could have been composed only in an aristocratic society where there was sufficient leisure for invention and where expert scribes were available to copy them into the beautiful manuscripts that have survived. No accompaniment is indicated in the manuscripts; if any was used it was presumably improvised.

Polyphony: Solo Voice and Instrumental Accompaniment.—It was inevitable that this flood of melody should have influenced the composers of polyphonic music. The 13th-century motet, even though founded on a fragment of plainsong, shows this influence very clearly; and it becomes even more marked in settings of French words intended for secular use. Furthermore, delight in the sound of the solo voice encouraged 14th-century French and Italian composers to assign all but one of the parts in a polyphonic composition to instruments. In this way a new art of solo song with accompaniment arose and continued to be practised throughout the 15th century. This art was inevitably more elaborate than the melodies of the *trouvères* and in some cases became highly mannered, creating a problem which has faced all songwriters—how to do justice to the words while at the same time allowing the music to develop to its fullest capacity.

Though there was often considerable elaboration in the instrumental parts of these compositions, on the whole they were dominated by the vocal line. But in the course of the 15th century composers of polyphonic music for voices came more and more to integrate their works by the use of imitation, and this practice spread to the composition of solo songs, with the tune sung either by an inner voice (particularly popular in Germany) or by the soprano, accompanied by instrumental parts based on fragments of the melody. At the same time, about the end of the 15th century, there was a reaction against elaborate polyphony in the shape of songs with the simplest possible accompaniment, a large number of which were composed in Italy (under the name *frottola* [*q.v.*]) and also in Spain. In songs of this kind, accompaniment by an instrumental ensemble was hardly necessary and it was often replaced by a single part for the lute. No doubt it was the popularity of these arrangements, many of which were published, that encouraged Spanish composers in the 1530s to write original songs with an accompaniment for the *vihuela* (a flat-backed instrument, tuned and played in the same way as the lute). This accompaniment could be quite simple, but the virtuosity of performers was an inducement to write varied accompaniments which offered a challenge to the accompanist without in any way interfering with the simplicity of the vocal line.

French composers of the 16th century remained faithful to the *chanson* (*q.v.*) for several voices, though many of these were also published in transcriptions for voice and lute. In England the old tradition of solo song with imitative accompaniment for an instrumental ensemble survives in William Byrd's *Psalmes, Sonets, and songs of Sadnes and pietie* (1588), though these were published with words added to the instrumental parts. Other English composers of the period, around the end of the 16th century, wrote original songs with lute accompaniment, some of which were also made available for singing by four voices.

Recitative and Aria.—By this time the Italians had developed a different manner of setting and accompanying words. This arose from the fact that composers of madrigals in Italy (*see* MADRIGAL), unlike their English imitators, had generally set distinguished poetry. The importance of the words in singing is suggested by B. Castiglione's reference in 1528 to *cantare alla viola per recitare; i.e.*, singing a solo song with instrumental accompaniment. In the course of the 16th century there was a growing feeling that the intricacy of the madrigal did less than justice to the words, though composers often avoided complication for short periods by making all the voices sing the same words at the same time. But homophonic writing, as opposed to polyphonic elaboration, did not solve the problem of allowing the words to be "recited" as if they were spoken. Hence toward the end of the 16th century a new style of word setting developed in which a single voice had complete freedom of time and expression, and the accompaniment, the simplest possible, was provided by a continuo instrument, on which

the accompanist improvised the chords indicated by a figured bass (*see* Thorough Bass). This style was known as *stile recitativo* and subsequently simply as *recitativo* or "recitative."

This manner of singing was ideal for dramatic performance and it was adopted in the first operas, at the end of the 16th century. It was not intended to be simply a translation of speech into song; the composers were too near to the madrigal, which continued to be written in the early 17th century, to ignore the possibilities of expression in vocal music. At the same time it was realized that occasional lyrical pieces were appropriate in the pastoral setting of these early operas; and when recitative was employed in the concert room it became obvious that the variety achieved by alternating recitative with song (or *aria*) was indispensable. Though recitative could be intensely moving when performed by a first-rate actor, the purely musical pleasure afforded by the aria was obviously more attractive to the average members of an audience, and it also offered more opportunities to a singer. Hence the aria came more and more to dominate opera and also oratorio; it also became very much extended by the use of instruments other than the continuo to alternate with the voice or to work in close association with it. The need for a significant musical structure on a large scale led to the *da capo* aria in three sections, the third of which was the same as the first, apart from ornamentation or elaboration of the vocal melody, which was left to the singer. The fact that this repetition of the first section sometimes made nonsense of the words does not seem to have unduly disturbed either composers or audiences, though protests against it were heard from time to time in the 18th century. The *da capo* aria, however, was not universal; there are many examples of shorter arias without this repetition.

Strophic Settings.—Outside the world of opera, the simple strophic song, with keyboard accompaniment, continued to thrive—notably in England, France, and Germany. In England it earned a new lease of life through the popularity of *The Beggar's Opera* (1728) and its successors, and in France its introduction into popular comedies in the early 18th century led to the creation of *opéra comique* (*q.v.*), which, unlike Italian *opera buffa*, remained faithful to spoken dialogue. The idea that such songs, as opposed to the operatic style of the solo cantata, could be a medium for artistic expression, was hardly realized in the 18th century. The songs of Haydn and Mozart are for the most part little more than simple ditties, though Mozart's "Das Veilchen" and "Abendempfindung an Laura" pointed to the possibilities of a deeper art of expression. It was Schubert who, beginning by imitating the narrative ballads of his immediate predecessors, showed what could be done to turn even the simplest strophic song into something more than an agreeable entertainment, and in the songs of his last year, such as "Der Doppelgänger," outstripped all his contemporaries in his power of dramatic realization. His example was not lost on the Romantic composers of the 19th century—among them Mendelssohn, Robert Schumann, Franz Liszt, and Brahms—who learned from him not only the art of varying a strophic melody but also the significance that could be given to the accompaniment. For Hugo Wolf the accompaniment often became a piece of music in its own right, allowing the voice to follow a rhythm dictated by the words and to achieve its own expressive melody without being fettered to the piano.

Problems of Songwriting.—Since that time there have been few composers of any country who have not at one time or another felt impelled to face the challenge of songwriting. The nature of the challenge is obvious enough. Inspired music, as Schubert showed, can often redeem inferior words; at the same time fine poetry may appear so self-sufficient that to add music to it is to spoil it. There is also the problem that the rhythm of spoken verse is normally more subtle than that of music, however ingeniously the composer may try to match it; and the more ingeniously he tries, the greater is the danger that music may abrogate its rights and become merely a vehicle for the poem. Italian recitative of the early 17th century solved the problem by allowing the singer complete freedom, adding only the simplest accompaniment. But however effective this may be in an opera, it risks undermining the musical structure of an independent piece.

In the long run there is no ideal solution. A continuous texture in the accompaniment may serve to unify the music, but it may also deny the singer the opportunity to make the words sound convincing as music. At first sight a strophic setting seems almost like an avoidance of the problem and may easily be regarded as much the easiest way of writing a song. In fact it is one of the hardest forms of songwriting, if it is to achieve anything like fidelity to the words. There are, however, ways of modifying a simple strophic scheme by varying the melody or the key or both; in exploring these possibilities Schubert showed incomparable skill.

The influence of language on song is not unimportant, particularly as songwriting in its turn often influences instrumental composition. The *da capo* aria grew out of the Italian language, for which it was the ideal medium. When the same style was borrowed by German composers the result was apt to be less successful. All French songwriting has a character of its own, since the language, unlike Italian, German, and English, has no regular tonic accent. This means that syllables can be set equally well on accented or unaccented beats; it also results in a peculiar fluidity which is absent from the regular accents of German song. It would seem likely that this fluidity is at least partly responsible for the shifting, kaleidoscopic harmonies which are one of the features of Gabriel Fauré's songwriting. In the same way the dramatic realism of Mussorgsky's songs is not merely an expression of his own temperament but also a consequence of the actual sounds of the Russian language. Something similar is to be found in Czech songwriting, where the lightweight syllables of the language suggest a similar treatment in the music.

Whatever the origins of song may be in remote antiquity—as a means of attracting attention, or telling a story, or providing encouragement in war or the chase—in civilized society it has developed as a natural response to the beauty of the human voice. Hence the melodic style of a song is liable to sound distorted if the capacity of the voice for phrasing and for blending syllables is ignored. Wide leaps are within the capacity of any trained singer and have often been used by composers of many different periods in the interests of dramatic intensity. But a vocal line which consists almost entirely of leaps can hardly be described as vocal and is certainly not a line. There is a tendency among mid-20th-century composers to treat the voice as if it were an instrument capable of negotiating a leap and still preserving its characteristic tone. A song of this kind, however dramatically it may express the words, is often ineffective because the singer has no opportunity to use his greatest asset—beauty of tone. Few composers have also been solo singers, but it is open to any composer to acquire an intimate acquaintance with the capacity and the sound of the human voice. The most successful modern songwriters have been those who either had such an acquaintance or were gifted with the instinct that made it unnecessary.

See also Singing and references under "Song" in the Index.

(Ja. A. W.)

SONGBIRD. Besides the application to any bird that sings, the term songbird has a restricted, precise meaning in bird classification. The true songbirds comprise the more than 50 families of the suborder Passeres or Oscines, which includes most of the great group of perching birds called the Order Passeriformes. They are well represented by many common garden birds such as sparrows, warblers, thrushes and wrens.

General Description and Natural History.—These birds vary in size from tiny kinglets and sunbirds to comparatively large crows. They are land birds that live in a wide variety of situations, from open grassland to forest. While songbirds include some of our best songsters such as thrushes, some have harsh voices like crows, and some do little or no singing. Their main food includes insects, worms, seeds and fruit picked up from the ground or from among vegetation, depending on the species. However, some like the swallows are very capable flyers and catch insects on the wing. Others, as the dippers, seek their food underwater in streams, and shrikes may catch mice and small birds.

In many species the birds pair at nesting time. The nest is

most often a cup-shaped structure. However, a hanging nest is made by some species and a tunnel excavated by others. The number of eggs may vary from one, in some tropical species, to as many as a dozen in some titmice. In colour the eggs range, depending on the species, from immaculate chalky white and light tints to deeper tones, and many are speckled and marked. The young hatch with a scant covering of down at most and in a blind, nearly helpless condition. They are cared for in the nest for a time and reach full size and are able to fly well a short time after leaving the nest. Many northern species migrate to a milder climate for the winter. The greatest number of species of songbirds is in the tropics, but they are also well represented in temperate zones. A few live in the arctic, but there are none in the antarctic.

Songbirds are distinguished from the other perching birds by certain anatomical characteristics, especially the more complicated vocal organ or syrinx (*see* below).

Bird Song.—Vocalization in birds includes a wide variety of calls besides the song proper and provides a means of social communication. Man is the only other animal that exceeds birds in the use of voice, and probably no other animals approach birds in this ability. Bird song is best considered the vocalization that is used in courtship and breeding, chiefly by the male, to advertise that he is ready to mate, to attract the female and perhaps stimulate her sexually, to keep the pair together and to inform rival males that he has established a territory from which they will be excluded. The male's calls are also part of a threat display that takes the place of actual combat in repelling intruding rivals. However, similar song is sometimes given spontaneously when there is no obvious use for it. Occasionally females sing, and especially in tropical species pairs may duet, again perhaps a method of reinforcing the bond between the pair. Often the song is delivered from a series of regularly used perches. Some species, especially those that live in grasslands, have flight songs.

In some birds other forms of sound-making have taken the place of vocalization in part at least, as in the woodpeckers which drum out a tattoo by pounding on a dead branch with their bill. Some grouse drum with their wings, others stamp their feet. The winnowing or bleating of the snipe in courtship flight is caused by air passing between the outer tail feathers; peacocks rattle their quills in courtship. (*See* COURTSHIP, ANIMAL.)

Song need not be pleasing to the human ears. The hooting of an owl; the monotonously repeated phrases of the North American whippoorwill; the crazed, repeated whistle of a Malayan cuckoo that has given it the name of the brain-fever bird; and the African tinker bird's repeated notes, which from their resemblance to hammering on metal, have given the bird its name—all must be called songs. While the best songsters are true songbirds, some birds of other groups have pleasing or musical utterances, like the quavering trill of the screech owl and the cheery whistle of the bobwhite quail.

Which birds are the best songsters is a question that is subjective in part. Although national pride and pleasant associations surely have an effect, there is general agreement on certain species. The nightingale of Europe (*Luscinia megarhynchos*), which is a small thrush, perhaps heads the list of famous songsters of literature. Its beautiful brilliant song, full of sweet trills, fluted notes and liquid phrases in surprising variety, is rich and loud. The melody is often enhanced by being delivered at night when all else is still. The European skylark of the poets (*Alaudia arvensis*) soars up, singing as it goes, until it is a mere speck in the sky alternately fluttering and sailing, pouring out its joyful and melodious song. Another outstanding songster is the European blackbird (*Turdus merula*), one of the thrushes.

In North America the mockingbird (*Mimus polyglottos*) is a wonderful performer with a rich, melodious, long-continued song. It consists of a great many phrases with notes repeated two or three times. Imitations of other birds are often incorporated into the mockingbird's song, and on moonlit nights the bird may sing almost until dawn. Among the finest songsters are the cardinal (*Richmondena cardinalis*), with its loud clear whistles in crescendo and accelerando; the hermit thrush (*Hylocichla guttata*), with silver bell-like quality to its serene song. Townsend's solitaire (*Myadestes townsendi*) is another thrush, whose superb song consists of clear, brilliant, ringing notes that rise and fall in pitch and volume as the bird warbles and trills.

In Australia the lyrebirds, which are not true songbirds, have songs that are superlative in variety and intensity and have a dramatic quality. The pied butcherbird has a richly musical flutelike song. The brown honey eater has a song remarkably like that of the European nightingale's, and divides his song into proper stanzas.

C. Hartshorne has elaborated the concept of bird song as music. He shows there is a measure of congruity between songbirds' feeling for sound patterns and ours. Birds have in unequal degree an actual musical ability and sensibility, and their song can be considered a primitive form of music, an evolutionary anticipation of human music. Of the approximately 9,000 species of birds perhaps only a third should be considered singing species. Of these perhaps 1,200 might be said to have fairly good songs and only 225 species, scattered over the world, have really outstanding songs. Of the outstanding songsters there are 26 in Europe, 21 in North America and about 20 in Australia. It is possible that there are more outstanding bird songs in the mountains of the tropics than elsewhere.

Music consists predominantly of tones rather than noises, *i.e.*, of relatively pure sounds of a single frequency or with natural harmonies instead of miscellaneous blends of frequencies. While birds produce both noises and tones, the latter are more conspicuous in the better songs. Flutelike notes are common in bird song, though often of higher pitch than flutes. There are truly chime or bell-like, guitarlike and even organlike tones in bird song.

Bird song tends to be high pitched (this is perhaps correlated with birds' high rate of metabolism) and their hearing range somewhat surpasses ours. Notes tend to be very short and arranged in some kind of pattern. It is true that some songs are repeated over and over with slight variation, but almost always there is a pause between songs. The birds may have a shorter attention span

(A) Interior view of the syrinx and (B) an exterior side view of the syrinx

and weaker memory than we have, and the monotony of certain of their songs is, therefore, heard by our ears rather than the bird's. It is significant, too, that the birds' songs that rate highest with us have a certain randomness, a quality of unpredictability. The wood thrush (*Hylocichla mustelina*) has about ten songs, which can follow one another in about 90 combinations; the bird improvises scores of different contrasts in a few minutes' singing. According to Hartshorne there exists one radical inferiority in the best bird songs, when compared with human music, and that is their great simplicity in length, shown by the brief time span of the motifs or musical units. The longest seems to be about ten seconds and only a few extend to six seconds. The average is probably less than three seconds. It is true that some birds have a repertoire that extends through a minute or two of uninterrupted singing, but these repertoires consist of discrete elements each lasting a few seconds at most. Other birds have a single song lasting a minute or longer, but this, like some insect songs, is a relatively patternless prolongation of a single sound, trill or buzz.

As well as having a primary biological function in the breeding season, when bird song reaches its height, some bird vocalizing

appears to be secondarily a leisure activity or play, an effusive burst of song out of sheer joy. This is especially evident in such birds as the white-throated sparrow (*Zonotrichia albicollis*), which sings on migration; the many species that sing in the autumn; and such birds as the Carolina wren (*Thryothorus ludovicianus*), which may sing every day of the year. This off-season singing may be the species' song at its very best.

Bird song shows every elementary rhythmic effect: accelerando (field sparrow, *Spizella pusilla*), ritardando (yellow-billed cuckoo, *Coccyzus americanus*), crescendo (some thrushes), interval inversion, simple harmonic relations, retention of melody with change in key and theme with variations. Bird song, according to Hartshorne, is always intelligible as simple music. The best singers are those with more variety and complexity in the use of elementary musical devices, and they seem to sing most.

FIG. 2.—SYRINX OF SOME DUCKS HAS AN ENLARGED, BONY CHAMBER

As found in (A) mallard, (B) pochard, (C) goosander, (D) steller's eider, (E) velvet scoter, (F) male and (G) female common scoter

Bird songs have been recorded in various ways, by musical notation, by graphic notation, by fitting words to the song, by describing it in words and by capturing it on tape or phonograph disc. But a most useful way for analyzing and comparing bird song is the sound spectrograph which turns the song into a visual pattern recorded on paper. One of the important uses of this, by W. H. Thorpe of Cambridge university, was in a study demonstrating that in some birds the song is innate, while in others it is partly innate and partly learned from others of the same species. This learning takes place only in the early part of the bird's life.

Vocal Organs.—The syrinx, as the voice-producing structure or song box is called, is located at the point where the windpipe divides into two bronchial tubes to go to the lungs. (*See* fig. 1.)

The syrinx is an intricately constructed organ with a firm bony framework and filmlike vibrating internal membranes over which the air, during exhalation, passes rapidly, producing all the many utterances of the bird. A variable number of syringeal muscles and their controlling nerves adjust the tension on the membranes. The song box reaches its greatest complexity in the true songbirds. But it is not a complicated syrinx alone that determines singing ability, for some true songbirds hardly sing at all.

FIG. 3.—ELONGATED WINDPIPE

(A) Enclosed in the sternum of a crane and (B) elaborately coiled in a manucode, one of the birds of paradise

In certain ducks, especially in the males, the syrinx has an enlarged, bony chamber (*see* fig. 2). However, none of these birds have elaborate voices, though the male's voice may be different from that of the female. Sometimes the windpipe is elongated and elaborately coiled. In some cranes and swans this elongation is enclosed within the breast bone or sternum. In certain of the birds of paradise known as manucodes the elongated windpipe is coiled on the breast between the skin and the flesh (*see* fig. 3). Presumably this lengthening of the windpipe gives resonance to the voice.

SONGHAI (Songhoi, Songhay, Sonrhai), a tall, dolichocephalic Negroid people of probable Caucasoid admixture. Probably originating in the region of Lake Chad, they inhabit the northern area in the bend of the Niger River in the Republic of Mali, extending from Lake Débo to the mouth of the Buni N'kebbi River in Nigeria. Composed of many related groups, the most important being the Djerma (Zerma), they numbered about 800,000 in the 1960s. Berbers founded (7th century A.D.) the ruling dynasty of the Songhai; their Gao empire passed under the domination of the Mali empire (*see* Malinke) in the 14th century, and was consolidated in the 15th century by the Songhai prince of Gao, Sonni Ali, and his successors. A Moroccan invasion in 1591 began crumbling this empire, and was followed by Bambara and Fulani (*qq.v.*) invasions, and finally by French occupation of Tombouctou (1893). Songhai conversion to Islam dates from the 11th century, influencing their culture and laws, as well as religion (*see* Africa: *History: Sahara and Sudan*). Songhai language forms an independent stock.

Based on family relationships, Songhai society also has social groupings of slaves, artisans and *griots* (bards and chroniclers), freemen and headmen. Cultivation, largely based on cereals, is practised intensively only during the rainy season from June to November; cattle are reared on a small scale and fishing is the quasi monopoly of the Mandingo-speaking Bozo (Sorko). Each craft of workers in iron, wood, pottery, leather, or cotton, belongs exclusively to one particular caste. The wealth of the Songhai is a result of their privileged trading position at the crossroads of west and central Africa. In the 1960s many young Songhai were leaving home for the coast, especially Ghana. *See* also Mali, Republic of; Niger, Republic of the; Tombouctou.

SONGKHLA (formerly called Singora) is a port city and capital of a *changwad* (province) of the same name on the east coast of peninsular Thailand. Pop. (1960) 31,014. Situated at the outlet of Thale Sap, the largest freshwater lake in Thailand, Songkhla is one of the largest cities in Thailand. It serves as a regional centre for the coastal area fronting on the South China Sea, as a port of call with a roadstead harbour, and as a centre for both fresh- and salt-water fishing. Trucked to Ban Hat Yai (Haad Yai), fish are shipped fresh by rail 133 mi. (214 km.) to Penang, Malaya. There are several ice manufacturing plants in Songkhla.

Located on a rail spur about 20 mi. from Ban Hat Yai but about 450 mi. from Bangkok, Songkhla is oriented commercially to the ports of Penang off the west coast of Malaya and Singapore at the southern end of the Malay Peninsula. Chief exports are rubber, tin, coconuts, peanuts, and forest and fish products.

In addition to being an economic and transportation centre, Songkhla has cultural, educational, and resort facilities. Among the educational institutions are a two-year teachers' college and a four-year technical institute.

With an area of 2,576 sq.mi. (6,672 sq.km.) and a population of 500,285 in 1960, Songkhla *changwad* has a population density of about 150 persons per sq.mi. It receives about 90 in. (2,286 mm.) of rainfall annually and has no distinct dry season. Rice is grown in the eastern part, and rubber trees are concentrated in the western section on the higher and better-drained soils. Some tin is mined. Songkhla is one of the most prosperous *changwads* in Thailand. (T. F. B.)

SONG OF SONGS: *see* Solomon, Song of.

SONNEBERG, a *Kreisstadt* (county capital) of East Germany in the *Bezirk* (district) of Suhl, German Democratic Republic. Pop. (1964) 29,811. The town lies at 1,330 ft. (405 m.) above sea level on the southern slope of the Thüringer Wald

(Thuringian Forest) about 31 mi. (50 km.) SE of the district capital Suhl and 50 mi. (80 km.) S of Erfurt. It is a railway junction and a centre of the toy industry which is located in the nearby towns and villages. It has a toy museum in which toys from many countries and centuries are on display. Other light industries produce items for entertainments and festivals, porcelain, and electrotechnical goods. There are slate quarries nearby. Sonneberg received its municipal charter in 1317. The town district of Sonneberg-Neufang has the highest observatory in Germany, built in 1925 and 2,093 ft. (638 m.) above sea level.

SONNET. The sonnet is unique among the poetic forms that originated in Western Europe in that it has never since its inception gone entirely out of favour.

It appears to have taken form among 13th-century Sicilian poets experimenting with troubadour verses from Provence (*see* ITALIAN LITERATURE: *The Sicilian School*). From Sicily it spread to Tuscany and was taken over from Guittone d'Arezzo (*c.* 1235–94) by Dante for poems in the *Vita Nuova* (*c.* 1293) and by Petrarch, who, in his *Rime* for Laura, wrote probably the most famous of all sonnets. These established what came to be recognized as the "Italian" or Petrarchan form of the 14-line poem: an octave, rhyming *a b b a a b b a*, and a sestet with rhymes variously disposed but never including a final couplet. The line was the staple Italian hendecasyllabic. With few variants and aberrations, the verse or line of the sonnet has always been the staple line of the verse of its language: Alexandrine in French, iambic pentameter in English, and so on.

With other poetic forms evolved during the Italian Renaissance, the sonnet traveled through much of Europe. It was handled in Spain by the marqués de Santillana in the 15th century, and established there in the 16th by Juan Boscán and Garcilaso de la Vega. In Portugal, Luís Vaz de Camões treated it with a fine balance of fire and style. Jan Kochanowski introduced it to Poland, whence it passed, often generations later, to other Slavonic literatures. Like other Renaissance forms, the sonnet arrived comparatively late in Germany: through Georg Rudolf Weckherlin, who was much influenced by the poets of England, where he passed much of his life in the 17th century; and Martin Opitz, whose formulation (in 1624) of metrical and other poetic rules roused many other poets to imitation and emulation of sonnets among other forms admired in Italian, French, and other foreign literatures.

It was in the 16th century that the sonnet was introduced into England, first by Sir Thomas Wyat and then by Henry Howard, earl of Surrey (both of whom translated some of Petrarch's sonnets), and to France by Clément Marot and Mellin de Saint-Gelais. From such French sonneteers as Philippe Desportes and Guillaume Du Bellay, whose sonnets were translated by several English poets, including Edmund Spenser, a fresh impulse was given to the sonnet in England, and it entered on further developments. Both Wyat, whose handling of the sonnet otherwise contributed little to its characteristic history, and Surrey began to use a rhymed couplet at the end of the poem, and this practice, adopted by Spenser and others, led to the full "English" or "Shakespearean" form, consisting of three alternately rhymed quatrains and a closing couplet. Spenser, Sir Philip Sidney, Samuel Daniel, Michael Drayton, and others also developed the practice of composing sonnets in sequences, in which a general connecting notion of love for a lady is sometimes loosely organized by a hinted story of the progress of the love; occasionally, the sequential sonnets are further linked by repetitions of lines or rhyme sounds. In all the sequences, however, the finest achievement is usually in a few individually strong sonnets, such as Spenser's "Most glorious Lord of Life," which points toward the later extension of subject matter. The greatest of all sequences, Shakespeare's to the young man and the dark lady, is held together less by its supposed story, which different editors have been able to rearrange almost to taste, than by its underlying meditation on time and art, emotionally and philosophically considered; the love relationships are images, compared and contrasted with images drawn from the non-human natural world, relevant to this meditation.

By the time John Donne had written his religious sonnets (probably 1609–10), and Milton, reverting to a version of the Italian form, his sonnets on political, religious, social, and personal occasions (1642–58), the sonnet had been extended to embrace all the subjects of which it is capable—that is, nearly all the subjects of poetry. It is the astonishing genius of this short form that it can range from "light conceits of lovers" to considerations of man, death, time, and eternity without doing injustice to any of them. It is, of course, only a single aspect or experience of a theme that can be thus considered, and unity of substance, as of form, in the sonnet is one of its strengths. In English, the difficulty of rhyming and the resultant insistence on shape marked out by stressed rhyming syllables make of the form a clear, firm structure seemingly capable of holding any weight of thought or feeling. Milton's practice did much to emphasize this insistence on structure. In several sonnets, he limits the number of allowed rhyme sounds even further by using the same vowel sound in different rhymes. Thus, in "On the Late Massacre in Piedmont," the only two vowel sounds in the rhyming words throughout the sonnet are long *o* and long *a*—"bones"/"stones" and "cold"/"old" in the octave; "they"/"sway" and "sow"/"grow" in the sestet. In "Methought I saw . . ." the rhyme sounds in the octave are "(s)*ai*(nt)" and "(gr)*a*(ve)," and in the sestet "(m)*i*(nd)" and "(s)*i*(ght)"; and in "When I consider how my light is spent" they are "(sp)*e*(nt)" and "(w)*i*(de)" in the octave and "(n)*ee*(d)" and "(st)*a*(te)" in the sestet. Thus, though he often runs over and obscures the *volta* or "turn" between strict octave and sestet, Milton nevertheless hardens rather than softens the strong outline of unitary form in the Italian model.

At first sight the Italian form with its few allowed rhymes is the more difficult; its satisfying organization of octave and sestet has been compared to the rising and breaking of a wave. The greater freedom of the three quatrains in the English form, which may have as many as six rhyme sounds, is, however, outweighed by the extreme difficulty of the concluding couplet, which may be estimated from the fact that even Shakespeare often failed with it. This couplet must somehow seem to account for or correspond to the accumulated force of the preceding 12 lines and therefore needs rather the compressed power of Greek epigram than the sharp neatness of, for example, a satiric couplet. The effect when successful has been compared to the firing of an arrow after the tensing of the bow, as the mounting tension of Shakespeare's "Th'expense of spirit in a waste of shame" is startlingly released in

> All this the world well knows; yet none knows well
> To shun the heaven that leads men to this hell.

At its lightest a graceful gesture, at its most profound the sonnet can concentrate immense feeling into a shape which, making its way easily by its grace into the consciousness, there releases and expands its meaning.

The 18th century was not one of the full flowering periods of the sonnet, but William Walsh wrote some early in the century, Thomas Warton attempted a revival, William Cowper practised the form, and Thomas Gray on occasion (as on the death of Richard West) found its formal strictness a happy challenge to his temperament.

The English Romantics who had felt "the weight of too much liberty" found it

> pastime to be bound
> Within the sonnet's scanty plot of ground,

and Wordsworth's best sonnets (usually in the Italian form) are among the finest examples of the genre.

Keats's uneasiness with the "pouncing rimes" did not prevent him from writing some beautiful sonnets, but for him one of the main values of the sonnet was the influence of its organic structure in developing the great stanzas of his odes. In Shelley's "Ode to the West Wind," too, the sonnet form seems to have influenced the 14-line stanzas consisting of four sections of *terza rima* followed by a couplet using the fifth rhyme. Keats and Shelley thus drew attention to the seminal, rather than the actual, powers of the form. The strict sonnet was later beautifully handled in France by Baudelaire and J. M. de Heredia, and in England, Elizabeth Barrett Browning, in the once very popular *Sonnets from the Portuguese*, returned some way toward Elizabethan se-

quences. Experiment, however, was lively in England in the later 19th century. The 16-line poems of George Meredith's sequence *Modern Love* are developed from the sonnet, and Gerard Manley Hopkins wrote sonnets in sprung rhythm with "outrides" and extra "codas." Some of Hopkins' best poetry, however, is contained in sonnets of strict Italian form. The most distinguished 20th-century work in the kind is Rainer Maria Rilke's *Sonette an Orpheus* (1922). Some modern poets, among them E. A. Robinson, Robert Frost, and Sidney Keyes, have written sonnets, and it seems unlikely that this powerfully moving and evocative form of poetry is yet moribund.

See also articles on various writers mentioned; on ALEXANDRINE VERSE; TERZA RIMA; and on the national literatures.

The work of individual sonnet writers is best studied in the publications of the writers concerned and in critical studies of them. (C. M. I.)

SONNINO, (GIORGIO) SIDNEY, BARONE (1847–1922), Italian statesman and financial expert who was twice prime minister and who as foreign minister promoted his country's entry into World War I. He was born at Pisa on March 11, 1847; his mother was English. Entering the diplomatic service in 1867, he left it in 1873 to devote himself to political and social studies. On his own initiative he made exhaustive researches on the conditions of life of the Sicilian peasantry and the Tuscan métayage system. In 1877, in cooperation with Leopoldo Franchetti, he published a masterly work, *La Sicilia nel 1876*. In 1878 he founded a weekly economic review, *La Rassegna Settimanale*, which four years later he converted into a political daily newspaper, *La Rassegna*.

Elected deputy in 1880, Sonnino served for some months in 1889 as undersecretary of state for the treasury. In December 1893, at a time of severe financial crisis, he was entrusted by Francesco Crispi with the portfolio of finance, and his energetic measures averted national bankruptcy: when parliament objected, he did not hesitate to impose taxes by decree. He had to find money for the Ethiopian War and fell from office with Crispi after the disaster of Aduwa (March 1896). Assuming then the leadership of the opposition, he combated the Marchese di Rudinì's government and opposed the "democratic" finance of Luigi Pelloux's first administration. After the modification of the Pelloux cabinet (May 1899) he became leader of the ministerial majority and supported the attempt to introduce a more authoritarian form of government. On the formation of Giuseppe Zanardelli's cabinet (February 1901) he continued in opposition against the new left-wing Liberalism. He was prime minister from Feb. 8 to May 27, 1906, and again from Dec. 10, 1909, to March 29, 1910, but his temperament was too solitary and severe to win him much support in Parliament.

On Nov. 5, 1914, three months after the outbreak of World War I, Sonnino became foreign minister in Antonio Salandra's cabinet. He negotiated first with the Central Powers, hoping for territorial concessions from Austria-Hungary. When this approach failed, he turned to the Allies, though he saw that Serbia's plans for expansion interfered with Italy's. Without consulting Parliament he convinced the government that Italy should join the war on the side of Great Britain and France; and in May 1915 war was declared against Austria-Hungary. His territorial ambitions for Italy made him object to the Allies' bringing Greece into the war on their side; but he remained foreign minister both in Paolo Boselli's cabinet (under which Italy declared war on Germany in August 1916) and in V. E. Orlando's (from October 1917). He attended the Paris conference as second Italian delegate. Disappointed in his attempt to annex Yugoslav territory, he left Paris in a moment of temper. On the fall of Orlando's cabinet (June 19, 1919) he retired to private life. He died in Rome on Nov. 24, 1922. His *Discorsi per la guerra* appeared in 1922 and his *Discorsi parlamentari* in 1925.

See C. Montalcini, *Sidney Sonnino* (1926). (D. M. SM.)

SON OF MAN. In the Gospels Jesus often refers to himself as the Son of man in such a way that it becomes clear that this must have been a term that was well known and loaded with meaning before his time. There is no agreement, however, as to the origin of the idea and as to what extent these sayings of Jesus are to be considered as authentic.

In the Synoptic Gospels (Matthew, Mark, Luke) the sayings in which the term Son of man is used fall naturally into three categories:

1. Eschatological sayings in which the Son of man is depicted as the judge who is to come in glory with the clouds of heaven in order to judge the world (*e.g.*, Mark 8:38; 13:26; 14:62; Matt. 24:27, 37, 39, 44). In these sayings the Son of man is always referred to in the third person, and there is no clear indication that Jesus is identical with that eschatological figure. Only once (Luke 12:8 ff.; *cf.* Mark 8:38) is any relationship established between Jesus and the Son of man: "everyone who acknowledges me before men, the Son of man also will acknowledge before the angels of God."

2. Passages concerned with the suffering, death and resurrection of Jesus (*e.g.*, Mark 8:31; 9:31; 10:33 ff.): "the Son of man must suffer many things . . . and be killed, and after three days rise again."

3. A few sayings which refer to various aspects of the activity of Jesus: he "has authority on earth to forgive sins" (Mark 2:10), he "is lord even of the sabbath" (Mark 2:28), he is called "a friend of tax collectors and sinners" (Matt. 11:19) and he is homeless, having "nowhere to lay his head" (Matt. 8:20; Luke 9:58).

There is no relation whatsoever among these groups.

The first question that should be asked concerning these passages is that of their authenticity. In some cases it can be observed that parallel passages use a simple "I" instead of the title Son of man. Thus Matt. 10:32 uses "I" to replace the "Son of man" of Mark 8:38 and Luke 12:8 ff.; Matthew introduces "Son of man" in 16:13, a saying where Mark has "I" (8:27) But in most cases tradition is firm on the use of the term. Few scholars question the authenticity of the group 1 sayings. As for group 2, it is necessary to remember that they presuppose the events of Easter and may express the faith of the early church although afterward put into the mouth of Jesus. Other scholars admit the possibility that Jesus uttered these words also, because he must have foreseen the outcome of his conflict with the Jewish authorities. The third group also presents some difficulties, but for the most part the attempts to question the authenticity have not been successful.

As far as the first group is concerned, the implications of the term are comparatively clear on the background of Jewish apocalyptics. In Dan. 7:13 there is a reference to "one like a son of man" who was given dominion so that all nations should serve him, and mention is made of a judgment of the evil; later in the same chapter this figure is interpreted as being "the saints of the Most High" (*i.e.*, ideal Israel). It is a matter of dispute whether "son of man" here means just "a man" in general, which would be in accordance with common Aramaic and Hebrew usage, or is already an eschatological term. In later apocalyptics the latter is definitely the case.

The book of Enoch uses the title son of man to denote an eschatological figure who is to come at the end of the present age to judge the world and establish the Kingdom of God. He is referred to as existing before the creation of the world and as being kept hidden with God until his appearance at the consummation of the age. Certain motifs connected with this figure seem to be influenced by the Iranian idea of the First Man, Gayomart (*see* ZOROASTRIANISM: *The Zoroastrian Religion: Cosmology*) which is also reflected in certain (later) Gnostic speculations. It is a disturbing fact, however, that the son of man passages in the book of Enoch are all in the part of the book commonly referred to as the Similitudes, of which there remain no Greek fragments and which does not seem to be represented among the fragments from the Qumran caves. (*See* ENOCH, BOOKS OF: *I Enoch*.) This suggests to some scholars that these passages may be later, perhaps Christian, interpolations. However, II Esdras, which derives from the time immediately after the fall of Jerusalem in A.D. 70, testifies to the existence of the term in Jewish apocalyptics, and it would probably not have been introduced there after the title had been used by Jesus.

In the third group, one or two of the passages might be explained by assuming the meaning of "man" in general, or especially "mortal man," as is the case in a number of passages in Ezekiel, where the prophet is addressed as "son of man." Matt. 11:19 is associated with the humble state of Jesus and may be connected with the suffering passages.

The idea of the suffering of the Son of man, represented by the second group of sayings, presents the most difficult problem. It is a matter of dispute whether or not the book of Enoch knew the idea of a suffering Son of man. There is no unambiguous evidence, and those scholars who find this idea represented reach their conclusion only on the basis of the fact that the Son of man has several features in common with the Servant of the Lord as described in Isaiah 40–55 (Deutero-Isaiah; *see* ISAIAH, BOOK OF). But these common features are positive—his election, his function as a lawgiver and as a light to the nations and the hope of the holy ones, etc. The suffering of the Servant is not referred to in connection with the Son of man, and the contemporary Jewish method of biblical interpretation does not favour the assumption that the figure of the Servant was adopted in its totality; therefore, nothing warrants that the glory of the Son of man presupposes his suffering. The mention of "the blood of the righteous one" in Enoch 47:1–4, immediately following a chapter dealing with the glory of the son of man, is no conclusive evidence, and the text itself is not even certain.

Thus, if Jesus did really use the title "Son of man" in connection with his suffering, it would seem that it was he himself who made the combination of the Son of man of apocalyptics with the suffering Servant of Deutero-Isaiah. He may even not have known the book of Enoch but interpreted his mission in terms of Dan. 7, Isa. 53 and perhaps also the suffering righteous of Wisdom 2–5.

It has also been suggested that the term might derive from Ps. 8:4 and 80:17, where it is taken to refer to the king; since the messianic hope developed out of the idea of an ideal king, the term therefore from the beginning would have been a "messianic" title. (*See* MESSIAH.) Ps. 8:4 is quoted in the New Testament as referring to Christ, but there is no evidence that Jesus applied these psalms to himself.

As a title of Christ the term "Son of man" seems to have lost currency rather soon. By far the most instances occur in the Synoptic Gospels. There are a few instances in the Gospel of John, referring to his preexistence in heaven (3:13), his death (3:14; 8:28; 12:23, 34, etc.) and his function as a judge (5:27). Paul does not use it. It seems probable that it was introduced by Jesus himself, but that the early church found other titles more suitable to express its faith in Jesus as the saviour.

SONORA, a northwest state of Mexico. Pop. (1960) 783,378; area, 71,403 sq.mi. (184,934 sq.km.). Sonora is bounded north by the United States, east by Chihuahua, south by Sinaloa, and west by Lower California and the Gulf of Lower California. Until the 1940s Sonora was primarily a mining area, producing copper, gold, and silver. Climatic conditions are generally arid to semiarid, and irrigation is necessary to produce winter vegetables, cereals, cotton, tobacco, and maize.

The state's population is clustered around Nogales, at the border, Hermosillo the state capital, a neat and thriving air, highway, and rail centre in the midst of a flourishing cotton district, Guaymas, a coastal deep-sea fishing resort, and Ciudad Obregón, in the heart of the Yaqui Valley. The latter grew in the 1950s from a barren crossroads town to a booming city of 70,000, with modern architecture, airport, and a large number of cotton-enriched farmers. Irrigation provided by the Alvaro Obregón Dam (completed in 1952) on the Yaqui River made this expansion possible by supplying water to more than 500,000 ac. (202,000 ha.) of desert land.

The area of Sonora was explored in the 1530s, and later became a famous colonial mining district. The small town of Alamos is a quaint reminder of this colonial past. In 1830 Sonora became a Mexican state, but the unruly Yaqui tribes were not finally subdued until the 20th century. The primitive Seris still follow their old way of life on the offshore island of Tiburón. The state derives its name (sonorous) from its deposits of grayish marble, which when struck emits bell-like sounds. (J. A. Cw.)

SONSONATE, a department in western El Salvador established in 1855, bordering the Pacific Ocean. Area 459 sq.mi. (1,189 sq.km.). Pop. (1961) 166,932. The population is concentrated on southern mountain slopes, the hot coastal lowlands having few people. In the north, Izalco volcano, a black symmetrical cone without vegetation (altitude 6,183 ft. [1,885 m.]) and the most active in Central America, erupts at fairly regular intervals. The coastal lowlands produce 50% of the nation's balsam used in medicines. Sonsonate is important in the production of cheese, tobacco, coffee, sugar, pineapples, and cotton.

Sonsonate City (pop. [1961] 35,531), the departmental capital, was founded in 1524. Interesting features are El Pilar Colonial Church, an old cathedral with 17 cupolas of all sizes, and nearby the San Antonio colonial shrine visited every year by thousands of pilgrims seeking cures. Sonsonate is 41 mi. (66 km.) W of San Salvador by highway and 12 mi. by road and railway from Acajutla, an open roadstead port which handles about 20% of the country's foreign trade. (C. F. J.)

SOOCHOW (SU-CHOU, WU-HSIEN), a city in Kiangsu Province, China, situated on the Yangtze delta, 36 mi. S of the river, 55 mi. W of Shanghai and close to the eastern lake shore of T'ai Hu. It probably dates from about 484 B.C., and, like other old towns nearby, was located upon onetime hilly coastal islands, which were later joined together by Yangtze silting plus man's diking and draining for at least 3,000 years. The scenic mass of lakes and canals, including the Grand Canal, caused Europeans to name it the "Venice of China," while the Chinese esteemed its beautiful gardens and fair women. It was the capital of the Wu Kingdom in the 5th century B.C. The fertile rice and silk country created wealth which over the centuries was poured into the construction of more than 200 private gardens, many restored and maintained for public enjoyment. Water, fertile soil, a mild climate for vegetative growth, nearby eroded lake stone, and leisure for scholarly study and aesthetic development raised gardening in Soochow to one of China's great arts. It was a place of official retirement, inspiration to poets and painters and a luxury handicraft centre for jade and ivory carving, silk weaving, and embroidery. Under T'ai P'ing control (1860–63) Li Hsiu-ch'eng instituted numerous social and economic measures that, unlike T'ai P'ing programs elsewhere, won the support of the local people and foreshadowed many of the changes of the Chinese People's Republic. It was a treaty port in 1896 and was held by the Japanese (1937–45). In modern times, silk filatures, weaving mills and a sericulture institute were set up. It is the seat of South Kiangsu Technical College. The city is on the Shanghai–Nanking railway and has a spur line south to Chia-hsing, Chekiang, augmented by highways for local traffic; some of the city's streets were widened for motor traffic. Pop. (1957 est.) 633,000. (TE. H.)

SOPHIA (SOPHIA ALEKSEEVNA) (1657–1704), regent of Russia from 1682 to 1689, the first woman to rule in Moscow since the time of Ivan IV's mother, Elena Glinskaya. She was born on Sept. 27 (new style; 17, old style), 1657, the sixth child of Tsar Alexis and his first wife, Maria Ilinishna Miloslavskaya. She received what was by Russian standards a remarkable education at the hands of Simeon of Polotsk, a Belorussian monk nurtured on the Jesuit humanism of the Polish academies. On May 7 (N.S.; April 27, O.S.), 1682, at the death of her brother Tsar Fedor III, her half-brother Peter I (*q.v.*) was proclaimed tsar; but Sophia could not abide the prospect of Russia's being ruled on Peter's behalf by the family of Naryshkin (*q.v.*), to which his mother belonged. The Miloslavskis, who shared Sophia's feeling, directed the discontent

of the *streltsy* (*q.v.*) or household troops against the Naryshkins while Sophia contrived to insinuate to both the Miloslavskis and the *streltsy* that the joint rule of her younger brother Ivan V (*q.v.*) and Peter, with herself as regent, was the best solution. On June 5 (N.S.; May 26, O.S.), what remained of the *Zemski Sobor* (Assembly of the Realm) ratified this proposal. Sophia began by bringing to heel the turbulent household troops. On Sept. 27 their self-appointed commander, Ivan Andreevich Khovanski, was executed on a charge of high treason; and the next month 12 out of the 19 Moscow regiments were sent to guard the frontier.

Reserving for herself the sphere of machination and intrigue, on all major issues of home and foreign policy Sophia consulted V. V. Golitsyn (*q.v.*) who was also her lover. In his absence she bestowed her favours on the new head of the household troops, Fedor Leontievich Shaklovity, the mainstay of her rule. In most respects her reign was one of continuance and compromise, as witness the treaty of "permanent" peace and alliance with Poland concluded in Moscow on May 6 (N.S.), 1686, and the Crimean expeditions of 1687 and 1689, both necessitated by the revival of the Turkish peril. The abolition of the customs barrier between Russia and the Ukraine was a further step in the incorporation of the Ukraine; Sophia also promoted industry and encouraged foreign craftsmen. In the "academy" established in Moscow in 1687 the Greek orientation triumphed over the Latin-Polish influence of Sophia's adviser, Silvestr Medvedev. In June 1687 Sophia adopted the style of autocrat; but her authority was shaken by the failure of the Crimean expeditions, the second of which was openly criticized by Peter. Knowing of Shaklovity's readiness to wipe out the Naryshkins, she complained of their enmity before the *streltsy*, hoping to provoke a repetition of the outburst of 1682. But in August 1689 enough of the *streltsy* colonels threw in their lot with Peter to ensure the Naryshkins' victory over the Miloslavskis. Shaklovity was executed, and on Sept. 17 (N.S.), Sophia's name was removed from the tsars' joint title. A week later she was obliged to enter the Novo-Devichi convent.

An abortive revolt of the *streltsy* in 1698, during Peter's absence, though not engineered by Sophia, was intended to achieve her reinstatement. On Oct. 22 (N.S.), 1698, she was tried by a special tribunal whose verdict is unknown, and on Oct. 31 she was compelled to take the veil. She died on July 14, 1704.

See C. Bickford O'Brien, *Russia under Two Tsars, 1682–1689* (1952). (L. R. Lr.)

SOPHISTS, the name given to certain Greek lecturers, writers, and teachers in the 5th and 4th centuries B.C., most of whom traveled about the Greek-speaking world giving instruction in a wide range of subjects in return for fees.

History of the Name.—The term "sophist" (Greek *sophistes*) had earlier applications. It is sometimes said to have meant originally simply "clever" or "skilled man," but the list of those to whom Greek authors applied the term in its earlier sense makes it probable that it was rather more restricted in meaning. Seers, diviners, and poets predominate in the list, and the earliest sophists were probably the "sages" in early Greek societies. This would explain the subsequent application of the term to the Seven Wise Men (7th–6th century B.C.) and to Pre-Socratic philosophers generally. When Protagoras is made by Plato (*Protagoras*, 317 a–b) to say that, unlike others, he is willing to call himself a sophist, he is using the term in its new sense of "professional teacher," but he wishes also to claim a continuous development from earlier sages to his own function as a teacher of wisdom. Plato and Aristotle altered the meaning again when they claimed that professional teachers such as Protagoras were not seeking the truth but only victory in debate, and were prepared to use dishonest means to achieve it. This produced the sense "captious or fallacious reasoner or quibbler" which has remained dominant down to the present day. Finally, under the Roman Empire the term came to be applied to professors of rhetoric, to orators, and to prose writers generally, all of whom are sometimes regarded as constituting what is now called the Second Sophistic movement (*see* below).

The 5th-Century Sophists.—The names survive of nearly 30 sophists properly so-called, of whom the most important were Protagoras, Gorgias, Prodicus, Antiphon (*qq.v.*), and Thrasymachus. Plato protested strongly that Socrates was in no sense a sophist—he took no fees and his devotion to the truth was beyond question. But from many points of view he is rightly to be regarded as a rather special member of the movement. The actual number of sophists was clearly very much larger than 30, and for about 70 years, until *c.* 380 B.C., they were the sole source of higher education in the more advanced Greek cities. Thereafter, at least at Athens, they were largely replaced by the new philosophic schools, such as those of Plato and Isocrates. Plato's dialogue, *Protagoras*, describes something like a conference of sophists at the house of Callias in Athens just before the Peloponnesian War. Antimoerus of Mende, described as one of the most distinguished of Protagoras' pupils, is there receiving professional instruction in order himself to become a sophist (*Protagoras*, 315 a) and it is clear that this was already a normal way of entering the profession.

Most of the major sophists were not Athenians but they made Athens the main centre for their activities, although traveling continuously. The importance of Athens in the movement was due in part no doubt to the greater freedom of speech there prevailing, in part to the patronage of wealthy men like Callias, and the positive encouragement of Pericles, who was said to have held long discussions with sophists in his own house. But primarily the sophists doubtless congregated at Athens because there they found the greatest demand for what they had to offer, namely instruction to young men, and the extent of this demand was not an accident. Athens itself was a democracy; while its limits were such that Thucydides could say that in fact Athens was governed by one man, Pericles, nonetheless it gave opportunities for a successful political career to citizens of the most diverse backgrounds, provided they could impress their audiences sufficiently in the council and the assembly. After Pericles' death this avenue became the highroad to political success.

The training which the sophists gave taught men how to speak and what arguments to use in public debate. A sophistic education was increasingly sought after both by members of the oldest families and by aspiring newcomers without family backing. The changing pattern of Athenian society made merely traditional attitudes in many cases no longer adequate. The criticism of such attitudes and the attempt to replace them by rational arguments was part of the especial attraction of the sophistic movement for the young, and it explains the violent distaste which they aroused in traditionalists. Plato thought that much of the sophistic attack upon traditional values was unfair and unjustified. But he learned at least one thing from the sophists—if the older values were to be defended it must be by reasoned argument and not by appeals to tradition and unreflecting faith.

Seen from this point of view the sophistic movement should be regarded above all as a function of Athenian democracy in the 5th century B.C. It offered an education designed to facilitate and promote success in public life. All the sophists appear to have provided a training in rhetoric and the art of speaking, and the sophistic movement was responsible for large advances in rhetorical theory and contributed greatly to the development of style in oratory. Sometimes in modern times the view has been adopted that this was the sophists' only concern. But the range of topics dealt with by the major sophists makes this unlikely, and even if success in this direction was the ultimate aim of their teaching in each case, the means adopted to promote such success were surely as much indirect as direct. For the pupils of the major sophists were offered instruction not merely in the art of speaking, but in grammar, in the nature of virtue (*arete*) and the bases of morality, in the history of society and the arts, in poetry, music, and mathematics, and also in astronomy and the physical sciences. Naturally the balance and emphasis differed from sophist to sophist, and some offered wider curricula than others. But this was an individual matter, and older attempts to divide the sophistic movement into periods in which the nature of the instruction given was altered are now seen to fail for lack of evidence. The 5th-century sophists inaugurated a method of higher education which in range and method can claim to have anticipated the modern humanistic approach inaugurated or revived at the Renaissance.

The Sophists and Truth.—A question still discussed is whether the sophists as a whole had any real regard for the truth and whether they taught their pupils that truth was unimportant compared with success in argument. Plato found against them on both counts and his hostile judgment is still frequently repeated without question. The Platonic writings make frequent reference to what Plato calls "eristic" and also to what he calls "antilogic"; the two have often incorrectly been treated as identical. Eristic for Plato consists in arguments aimed at victory rather than truth. Antilogic involves the assignment to any argument of a counterargument which negates it, and the full technical sense of the term includes the contention that both argument and counterargument are equally true. Antilogic in this sense was especially associated with Protagoras, but Plato, no doubt correctly, attributes its use widely to other sophists. He regards the use of antilogic as essentially eristic, whether it be used to silence an opponent by making his position seem self-contradictory, or whether it be used mechanically to establish the negation of any proposition put forward in debate. He concludes that the widespread use of antilogic in sophistic discussions is evidence that sophists had no real regard for truth, which must itself be free from antilogic.

But Plato himself believed, for much or possibly all of his life, that the phenomenal world was essentially antilogic in character, inasmuch as no statement could be made about it which would rank any higher in truth than the negation of that statement. For example, if a man is tall in relation to one object, he will also be short, and so not-tall, in relation to another object. In so characterizing the phenomenal world Plato would certainly not wish to be called eristic—he would regard the application of antilogic to the description of the phenomenal world as an essential preliminary to the search for the truth residing in the Platonic Forms, which are themselves free from antilogic.

This affects our judgment about the sophistic use of antilogic. To the extent that it was used irresponsibly to secure success in debate it can fairly be classed as eristic and the temptation so to use it must often have arisen. But where it was invoked because it was genuinely believed that what was being described in fact involved antilogic characteristics, or where it was used as a device for analyzing a complex situation in order to reveal its complexity, then antilogic was in no way inconsistent with devotion to truth. This raises the question to what extent the sophists possessed any general view of the world and to what extent they gave expression to any genuine philosophic views, whether original or derived.

Philosophy.—Ancient writers, influenced by Plato and Aristotle, seem to have excluded the sophists, apart from Protagoras, from their schematized accounts of the succession of early Greek thinkers. Modern writers have frequently maintained that, whatever else they were, the sophists were in no sense philosophers. Even those who acknowledge the philosophical interest of certain particular doctrines attributed to individual sophists often tend to regard these as exceptions, and claim that, as the sophists were not a school but only independent teachers and writers, as a class they must be denied the title of philosophers. Two questions are involved, whether the sophists held intellectual doctrines in common and whether some or all of these could fairly be called philosophic.

Among moderns, Hegel was one of the first to reinsert the sophists into the history of Greek philosophy. He did so within the terms of his own dialectic by treating them as representing the antithesis to the thesis of the group of philosophers known collectively as the Pre-Socratics. The Pre-Socratics sought the truth about the external world with a bold enthusiasm which produced a series of explanations, each laying claim to correctness. None of these explanations of the physical world paid any attention to the observer and each was driven to reject more and more of the phenomenal world itself as unreal. With the Eleatics this culminated in the paradox that little or nothing of the phenomenal world was left as real. This in turn produced a growing distrust of the power of human beings to attain knowledge of the ultimate basis of natural phenomena. Philosophy had reached an impasse and there was a danger of complete skepticism about the possibility of knowledge. This provoked the "antithesis" of the sophistic movement, which rejected the "thesis" of the objectivists and concentrated attention upon man rather than upon nature. The sophists were subjective idealists, and so philosophy could make a step forward by turning its attention to the subjective element in knowing. Reflection upon the contrast between the thought of the sophists and their predecessors produced the "syntheses" of Plato and Aristotle.

Hegel's schematization of Greek thought was rooted in his own theory of dialectic, and the details of his dialectic made little appeal to subsequent historians of Greek philosophy. But the essentials of the scheme which Hegel propounded have endured and are embodied in the majority of full-scale histories of early Greek thought. Whether any of the sophists were subjective idealists may be doubted. It depends in part on the vexed question whether Protagoras held that phenomena had subjective existence only, or thought that all things perceived had objective existence, although their perception depends upon the nature of the percipient and their relation to him. But it is fairly clear that the sophists did concentrate attention very largely upon man and human society, upon questions of semantics and epistemology, upon the importance of the observer and the subjective element in reality and in the correct understanding of reality. To that extent Hegel's appreciation may be accepted as valid.

This goes a long way to explain the philosophic hostility of Plato and Aristotle. Above all in the eyes of Plato, anyone who looks for the truth in phenomena alone, whether he interprets it subjectively or relativistically, cannot hope to find it there, and his persistence in turning away from the right direction virtually amounts to a rejection of philosophy and the search for truth. Many a subsequent thinker for whom metaphysics is the crowning achievement of philosophy has felt with Plato that the sophists are so antimetaphysical in their approach that they have no claim to rank as philosophers. But in a period when to many who would wish to call themselves philosophers metaphysics is no longer the most important part of philosophy and to some it is not a part at all, there is a growing appreciation of the interest to philosophers of a number of problems and doctrines which recur in discussions initiated by sophists in the 5th and 4th centuries B.C.

Morality.—In the 18th and early 19th centuries the standard view of the sophists was that they were charlatans. Coupled with the attempt to discredit their intellectual honesty was the claim that their doctrines were immoral and that they were responsible for the moral corruption of the youth of Athens and even for the beginnings of the decline of Greece from the high position reached in the 5th century. The basis for the charge was two contentions, both correct: first that many of the sophists leveled damaging attacks against the traditionally accepted moral code; and secondly that they explored and even commended alternative approaches to morality which would condone or allow behaviour of a kind inadmissible under the stricter traditional code.

Much less weight has been attached to these charges since about the mid-19th century. First, many of the attacks on the traditional morality were in the name of a new morality which claimed to be of greater validity. The attacks upon particular doctrines often claimed that accepted views should be abandoned as being morally defective. Secondly, even when socially unacceptable action appeared to be commended this was frequently done in order to introduce a point of principle which must be taken into account in any satisfactory moral theory. Thus when Thrasymachus in the first book of Plato's *Republic* takes up the position that justice is unwarranted when it merely contributes to another's good and not to the good of the doer, he is making a point which Plato accepts. In fact Plato devotes the rest of the *Republic* to the attempt to show that justice is essential for the achievement of the good of the person who is required to be just. Thirdly, there is no evidence that any of the sophists were immoral in their own lives or that any of their pupils were induced to immoral actions by their teaching. Rather the serious discussion of moral problems and the theory of morality tends to improve behaviour and not to corrupt it.

Writings.—In addition to their teaching the sophists wrote many books, whose titles are known from lists preserved by

writers such as Diogenes Laërtius, which probably derive from library catalogues. It has usually been supposed that the writings themselves hardly survived beyond the period of Plato and Aristotle, but this view requires some modification in the light of papyrus finds, admittedly few, that were copied from sophistic writings in the Christian era. It has been possible to identify also certain imitations or summaries of 5th-century sophistic writers, whose names cannot be discovered, in the works of later writers, of which the most important are the discussion of law in the *Protrepticus* of Iamblichus, and the so-called *Dissoi Logoi* found in the manuscripts of Sextus Empiricus. All this evidence suggests that while most later writers took their accounts of the sophists from earlier writers, especially Plato, the original writings did in many cases survive and were at least occasionally consulted.

Particular Doctrines.—As part of his defense of the sophists against the charge of immoral teachings, the historian George Grote maintained that they had nothing in common with each other except their profession, as paid teachers, qualifying young men to think, speak, and act with credit to themselves as citizens. This denial of common doctrines to the sophists cannot be sustained—the evidence is against it. While the sophists were not a sect with a set of obligatory beliefs or doctrines, they had in common an interest in a whole series of questions to which they sought to apply solutions along certain clearly defined lines.

Before attempting to state what some of these were, however, it is important to remark that there are great difficulties in the precise statement of individual sophistic doctrines. No complete writings survive from any of the sophists to check the accounts found in Plato, and later writers were often but not always dependent upon what they found in Plato. Plato doubtless knew well the doctrines of individual sophists but he was writing for those to whom these doctrines were already well known, and he was always more interested in following the argument where it led than in providing precise statements of other people's views for the sake of posterity. Consequently almost everything that is said about particular sophistic doctrines is subject to controversy and disagreement among scholars.

Relativism and Skepticism.—These have often been regarded as a common feature of the sophistic movement as a whole. But it was early pointed out that it is only in Protagoras and Gorgias that there is any suggestion of a radical skepticism about the possibility of knowledge, and even in their case Sextus Empiricus in his discussion of skepticism is probably right when he declares that neither was really a skeptic. Protagoras does seem to have restricted knowledge to what was derived from the senses, but he did believe emphatically that whatever was perceived by the senses was certainly true. This led him to assert that the tangent does not touch the circle at a point only, but along a definite length of the circumference; clearly he is referring to our perceptions of drawn tangents and circles. Gorgias, who claimed that nothing exists, or if it does exist, it cannot be known, or if it exists and is knowable it cannot be communicated to another, has often been treated as denying both all reality and all knowledge. Yet he also seems to have appealed in his very discussion of these themes to the certainty of perceived facts about the physical world, *e.g.*, that chariots do not race across the sea. Others dismiss his whole thesis as a satire or joke against philosophers.

Probably neither view is correct; what Gorgias seems to have been attacking was not perceived reality nor our power to perceive it, but the attempt to assign existence or nonexistence with the metaphysical implications of such an operation to what we perceive around us. There is evidence that others of the sophists, *e.g.*, Hippias, were interested in questions of this kind, and the most likely conclusion is that they were all to a greater or lesser degree concerned to reject the claims of any nonsensible existence after the Eleatic fashion. The sophists in fact were attempting to explain the phenomenal world without appealing to any principles outside phenomena. They believed that this could be done by including the observer within the phenomenal world. This refusal to go beyond phenomena was in Plato's eyes the great weakness in all their thinking.

Science.—A second common generalization about the sophists has been that they represent a revolt against science and the study of the physical world. The evidence is against this, inasmuch as for Hippias, Prodicus, Gorgias, and Protagoras there are records of a definite interest in questions of this kind. The truth is rather that they were in revolt against attempts to explain the physical world by appeals to principles which could not be perceived by the senses, and instead of framing new "objective" explanations they attempted to explain where explanation was required by introducing the perceiver as one element in the perceptual situation.

Nature and Law.—One of the most famous doctrines associated with the sophistic movement was the opposition between nature and custom or convention in morals. It is probable that the antithesis did not originate in sophistic circles but was rather earlier, but it was clearly very popular and figured largely in sophistic discussions. The commoner form of the doctrine involved an appeal from conventional laws to supposedly higher laws based on nature. Sometimes these higher laws were invoked to remedy defects in actual laws and to impose more stringent obligations, but usually it was in order to free men from restrictions unjustifiably imposed by human laws that the appeal to nature was made. In its extreme form this appeal to nature involved the throwing off of all restraints upon self-interest and the desires of the individual, and it was this more than anything else which gave support to charges of immoral teaching against the sophists. On other occasions the terms of the antithesis were reversed and human laws were explicitly acclaimed as superior to the laws of nature, and as representing progress achieved by human endeavour. In all cases the laws of nature were regarded not as generalized descriptions of what actually happens in the natural world, and so not like the laws of physics to which no exceptions are possible, but rather as norms which people ought to follow although quite able to do otherwise. Thus the appeal to nature tended to mean an appeal to the nature of man treated as a source for norms of conduct.

This appeal was not to Greeks anything very novel. It represented rather a conscious probing and exploration into an area where their whole tradition of thought had long suggested the true source lay for norms of conduct. If Callicles in Plato's *Gorgias* represents a position actually held by a living sophist when he advocates free rein for the passions, then it was easy for Plato to argue in reply that the nature of man, if it is to be fulfilled, requires organization and restraint in the licence given to the desires of particular aspects of it; otherwise the interests of the whole will be frustrated. Both Plato and Aristotle, in basing so much of their ethics on the nature of man, are only following out the approach begun by the sophists.

Religion.—The sophists have sometimes been regarded as characterized by their attacks on the traditional religious beliefs of the Greeks. It is true that more than one of the sophists seem to have had to face prosecution for impiety, as did Socrates also. Protagoras wrote "concerning the gods, I cannot know either that they exist or that they do not exist nor what they are like in form," and Prodicus offered a sociological account of the development of religion. Critias went further when he supposed that the gods were deliberately invented to inspire fear in the evildoer. It is thus probably correct to say that the tendency of a good deal of sophistic thought was to reject the traditional doctrines about the gods. Indeed this follows almost inevitably if it is right to suppose that they were all attempting to explain the phenomenal world from within itself, while excluding all principles or entities not in phenomena. But in their attitude to the Olympian deities the sophists were probably at one with most of the Pre-Socratic philosophers of the 6th and 5th centuries, and also most thinking people toward the end of the 5th century. It is thus probably misleading to regard them as breaking new ground in their attitude toward religious beliefs.

Sociology.—The importance which the sophists attached to man meant that they were extremely interested in the history and organization of human societies. Here again most is known about Protagoras and there is a danger of wrongly treating his particular doctrines as typical of the sophistic movement as a whole. In the 5th century a very common attitude saw human history in

terms of a decline from an earlier golden age. Another view supposed that there were recurring cycles in human affairs according to which a progression from good to bad would give way to one from bad to good. The typical sophistic attitude to society rejected both these views in favour of one which saw human history in terms of progress from savagery to civilization. In a famous myth Protagoras explained how man achieved civilized society first with the aid of arts and crafts and then with the gaining of a sense of respect and justice in the ordering of his affairs. The general direction of the thinking of most of the sophists seems, as far as there is any evidence, to be along similar lines.

Virtue Teachable.—One of the most distinctive doctrines of all the sophists was that virtue can be taught. This sprang naturally from the sophists' professional claim to be the teachers of young men throughout the cities of Greece. But the word for virtue, *arete*, implied to Greeks both success in living and the qualities necessary for achieving such success, and the claim that *arete* could be taught by the kind of teaching which the sophists offered had far-ranging implications. It involved the rejection of the view that *arete* came only by birth, for example by being born a member of a noble family, and it involved also the rejection of the doctrine that *arete* was a matter of the chance occurring of specified qualities in particular individuals. *Arete* on this view was the result of known and controllable procedures, a contention of profound importance for the organization of society. Moreover, what can be taught has some relation to what can be known and understood. The extreme contention of Socrates that virtue *is* knowledge, whatever exactly it meant, went beyond the normal sophistic position. But the belief that teaching with a large intellectual content could produce success both for the individual and for governments has had a profound influence upon the subsequent history of education. Once again, it is through the acceptance of this doctrine by Plato and Aristotle that the sophistic position came to be part of subsequent humanist tradition.

The Second Sophistic Movement.—It is a historical accident that the name "sophist" came to be applied to the Second Sophistic movement. Greek literature underwent a period of eclipse during the 1st century B.C. and under the early Roman Empire. But Roman dominance did not prevent a growing interest in sophistic oratory in the Greek-speaking world during the 1st century A.D. This oratory aimed merely at instructing or interesting an audience, and had of necessity no political function. But it was based on elaborate rules and required a thorough knowledge of the poets and prose writers of antiquity. Training was provided by professional teachers of rhetoric who claimed the title of sophists just as the 5th-century sophists had adopted a name which had already been used by others before them.

The revival of the Greek spirit under Hadrian and other philhellenic emperors in the 2nd century A.D. found expression in a fresh flowering of Greek prose writing following the principles developed and applied by the professors of rhetoric in the 1st century A.D. Hence a group of Greek prose writers in the 2nd century A.D. came to be regarded as constituting the Second Sophistic movement. This was a backward-looking movement which took as its models Athenian writers of the 5th and 4th centuries B.C.; hence the label "Atticists" applied to some of its leading members. The limits of the movement have never been precisely defined. It is usually taken to include Polemon, Herodes Atticus, Aelius Aristides, Maximus of Tyre, and the group of Philostrati. Dio Chrysostom of Prusa is often included, although others would regard him as preparing the way for the main period. Other writers, like Lucian, Aelian, and Alciphron, were influenced by the movement even if not properly to be regarded as members of it, and the writers of prose romances, such as Longus and Heliodorus, and the historians Dio Cassius and Herodian, are also associated with the general trend. By the 3rd century A.D., however, its impulse was weakening and by the end of the century it was no longer distinguishable within the general stream of Greek literature.

(G. B. KD.)

SOPHOCLES (497 or 495–406 B.C.), one of the three great Greek tragic poets, was born at Colonus, a village just outside Athens. The only ancient biography is a short anonymous account of unknown date, compiled from earlier biographies, and prefixed to most of the Sophoclean manuscripts—a mixture of bald fact, hypothesis and gossip. It can be supplemented from other ancient sources, but the result is meagre. All give a picture of a dignified, gracious and well-loved citizen who moved in good society and enjoyed the pleasures of life. His father, otherwise unknown, was Sophillus, perhaps a manufacturer of armour. He was wealthy and gave his son a good education: his master in music was Lamprus, the most distinguished musician of the day, and he is said to have studied tragedy (including no doubt musical composition and choreography) under Aeschylus. He was a beautiful boy, a good dancer, lyre player and wrestler. He was selected to lead a chorus of boys which performed a paean in celebration of the victory over the Persians at Salamis (480 B.C.). It is not known when he first competed in the dramatic festival; he gained his first victory in 468, defeating Aeschylus. This began a career of unparalleled success. An inscription of the 3rd century B.C. credits him with 18 victories, the Suda lexicon (10th century A.D.) with 24, while the *Life*, citing a writer of the 2nd century B.C., says that he won 20 first prizes, many second prizes and was never third. (The lowest of these figures may not have included victories won in the Lesser Dionysia.) Aeschylus won 13—but he died at the age of 68, and Sophocles was still writing at 90; Euripides won only three. Sophocles' most famous play, *Oedipus Tyrannus* (*Oedipus Rex*), brought him only the second prize; the prizes however were awarded not for single plays but for a tetralogy comprising three tragedies and one satyr play, and it may well be that the plays presented with the *Oedipus* were not first-rate. According to the Suda lexicon he wrote 123 plays—no unlikely number: it would correspond to about 30 trilogies, in a productive career of 60 years, and in mere bulk would not much exceed Shakespeare's output. Of his minor poems nothing remains.

BY COURTESY OF THE VATICAN MUSEUM

SOPHOCLES, ROMAN COPY OF A GREEK STATUE OF ABOUT 340 B.C.

Unlike Euripides, he played a distinguished part in the public life of Athens. In 443–442 he was Hellenotamias (president of the board that collected the tribute from Athens' subject-allies in the Delian league; *q.v.*). In 440 he was elected one of the ten strategoi (military and naval commanders) in the war against the revolted Samians; his senior colleague was Pericles. The Argument to the *Antigone* attributed to the scholar Aristophanes of Byzantium says that Sophocles owed his election to the impression created by the play. The statement can hardly have been more than a surmise; nevertheless it dates the *Antigone*. A story in Plutarch's *Life of Nicias* implies that Sophocles was elected

strategos a second time. The *Life* says that he served on embassies to foreign states, which is likely enough; also that he founded the *Thiasos ton Mouson* (which might be rendered "The Royal Society for Music and Literature," except that the patrons were the muses). Outliving Euripides (who was about 12 years his junior) by a few months, he died just before the disastrous end of the Peloponnesian War. The *Life* of Euripides says: "Sophocles, hearing that Euripides was dead, brought on his chorus and actors without their crowns, and himself put on mourning; and the people wept." Euripides had died at the court of Archelaus, king of Macedon; Aeschylus also had died abroad (in 456 B.C.), in Sicily; it was gratefully remembered of Sophocles that he had remained in Athens. In 405 Aristophanes produced *The Frogs*, in which Aeschylus and Euripides contend for the throne of tragedy in Hades, with Sophocles sitting by, ready to take on Euripides if he should win (which he does not); Aeschylus himself had offered the throne to Sophocles, but he had declined it, "courteous in Hades, as he had been on earth."

WORKS

Of Sophocles' works, there remain seven complete tragedies, about 400 lines of a satyr play, the *Ichneutai* (*Ichneutae*, "The Investigators") discovered in Egypt in 1907 on a papyrus written in the second half of the 2nd century A.D. and several hundred fragments of plays now lost. The fragments vary in length from a single word, cited by a grammarian or a lexicographer, to passages of 12 or 15 verses. The seven complete plays derive from a selection made by a scholar unknown at a date unknown—perhaps in Alexandrian times, and perhaps for school use. All are works of Sophocles' maturity, though (apart from the *Antigone*, which must have been produced in 441 or 442) only one is dated by documentary evidence: the *Philoctetes*, 409 B.C. Tradition, which there seems no good reason to disturb, makes *Oedipus Coloneus* a work of Sophocles' extreme old age; it is said to have been produced by his grandson. For dating the other plays we must depend on stylistic and metrical evidence—some of which is more hazardous with Sophocles than with, for example, Euripides. Sophocles' dramatic style was much more supple, and in some respects changes from minute to minute rather than from decade to decade. Contemporary allusions are also much rarer and more problematic than in, say, Euripides or Shakespeare. However, it is clear that the *Ajax* is the earliest of the seven; 447 ± 3 is a date that most scholars would accept. The *Trachiniae* was tentatively placed by R. C. Jebb between 420 and 410; later stylistic analysis places it much closer to the *Antigone*. For the remaining plays, *Oedipus Rex* and *Electra*, dates between 430 and 415 would be reasonable; the *Electra* seems to be the later of the two. The *Ichneutae* could be an early work, but the evidence available is not worth much.

Dramatic Style.—Ancient authorities credit Sophocles with dramatic innovations, most of them of minor importance. He invented *skenographia* (certainly not "scene painting," but probably some kind of device applied to the wall of the building at the back of the *orchestra*), and *periactoi*, which may have been revolving drums giving some indication of *locale*. The one major innovation—which, however, some authorities ascribe to Aeschylus —was the introduction of a third actor. It had always been permissible for the two actors to "double," but the addition of a third enabled the dramatist to increase the number of his characters, thereby making plot more fluid and situation more complex: Sophocles' finest scenes are those that involve the three actors at once, as for instance the messenger scene in the *Electra* (*see* below). Aeschylus in his later plays used the third actor to great effect, but in quite a different way, as when Cassandra is silent, though dramatically powerful, in the scene between Agamemnon and Clytemnestra. The difference is that the typical Aeschylean plot is linear; the Sophoclean, complexive. In the *Oresteia*, for example, Agamemnon takes vengeance on Paris, Clytemnestra on Agamemnon and on Cassandra, and Aegisthus on Agamemnon; Orestes avenges his father upon Clytemnestra and Aegisthus, and then has to contend with the avenging spirits of his mother. In such a drama characters collide rather than struggle with each other; they destroy, and are destroyed, in accordance with cosmic, and evolving, conceptions of retribution. There is little personal interplay; the characters are impressive in size and power, and therefore are not drawn in detail. The typical Sophoclean tragic action is one that is seen, as it were, not through the telescope but by the natural vision, though a vision that is assisted, and controlled, by the pervasive presence of gods. The chief agent does something involving grave error; this affects others, each of whom reacts in his own way, and thereby, perhaps, causes the chief agent to take another step toward ruin—his own, and that of others as well. The characters do struggle with each other; therefore they must be drawn in more detail. Peripheral figures too become involved in the central issue; plot must be more complex —though Sophocles avoids anything like subplot or decorative additions; the economy and concentration shown by his plays are most remarkable. This more complexive tragedy demanded a third actor. Equally, those who were to suffer from the tragic error were none of them of the next generation; all were present at the time. Therefore Sophocles abandoned the spacious Aeschylean framework of the connected trilogy; all was comprised within the single play. From then on, with very rare exceptions, "trilogy" meant no more than three separate tragedies presented at the same festival.

The development of character and plot naturally increased the histrionic and decreased the lyrical element in drama. Counting by lines, slightly more than one-half of the *Agamemnon* is either sung or chanted; of the *Antigone*, less than one-third, though this play is by far the most lyrical of the seven. But the chorus is still integral. No one formula can sum up its functions. As Aristotle remarked, in Sophocles the chorus is "a fellow actor"; therefore it will often share the illusions of other actors in the piece, as it does for instance in the *Antigone* and *Ajax*, where it takes, more or less, the point of view of Creon and Ajax respectively—that is, the wrong one. Sometimes it becomes the "ideal spectator," making philosophic comment (as in the solemn third ode of *Oedipus Rex*); sometimes it is a purely lyrical instrument, giving release from the tragic tension through the beauty of its dance and music.

Some of the odes, *e.g.*, the one just mentioned, or the second, third or sixth of the *Antigone*, place Sophocles in the front rank of Greek lyric poets. Of the music that he wrote nothing is known; about the choric dances this much can be inferred from their metres, that they must have been conceived in a very plastic fashion. As for the style of the spoken verse, it is reminiscent of Shakespeare's, responding directly to the dramatic needs of the moment; it is as far as possible from being a standard, uniform style, like Euripides'. It will be weighty or swift, intense or easy-going, highly-wrought or perfectly plain. It is no accident that Aristophanes, who parodied Euripides' and Aeschylus' style, left Sophocles' alone.

His Tragic Thought.—Sophocles has been universally admired for the sympathy and vividness with which he draws characters; especially notable are his tragic women: Electra, Antigone, Deianeira, Tecmessa and others. Also, few dramatists have been able to handle situation and plot with more power and certainty; the frequent references in the *Poetics* to *Oedipus Rex* show that Aristotle regarded this play as a masterpiece of construction, and few later critics have dissented. Further, he is unsurpassed in his moments of high tragic tension, and in his revealing use of tragic irony. In other respects there has been some tendency to compare him unfavourably with Aeschylus and Euripides: Sophocles, it has been said, was a supreme artist and no more; he grappled neither with religious problems like Aeschylus nor with intellectual and social ones like Euripides; he accepted the gods of Greek religion in a spirit of unreflecting orthodoxy, and contented himself with presenting human characters and human conflicts. Further, two of his plays, *Ajax* and the *Trachiniae*, have been adversely criticized in precisely that aspect of his art for which, elsewhere, he has been so much admired, namely in their structure: for though the *Ajax* seems to reach its natural conclusion in the suicide of the hero, the play continues with several scenes that concern the burial of his body;

while in the *Trachiniae*, if Deianeira is the central character, she too kills herself two-thirds of the way through and is subsequently hardly mentioned, while if Heracles is taken to be the hero, he does not even appear until his wife is already dead, when he himself also is on the point of death. For the "lack of unity" in the *Ajax* several inorganic explanations have been offered, the most naïve of which is that Sophocles was running short of material; about the *Trachiniae* the worst that can be said is that he simply combined two personal tragedies into one play.

The source of these misconceptions is the same. Sophocles did not write tragedies of character about individuals, but tragic drama about Man and the Gods; the religious element in his plays is not orthodoxy, not something added, out of personal piety, to a humanistic drama already complete; it is his presentation of the way in which the universe works—and it is worthy of attention. This is the reason why his gods are so stern, sometimes baffling, rarely benevolent; and the reason why he does not criticize them is that there is not much point in grumbling at the universe. Further, he did not, like Aeschylus and Euripides, make statements about his religious ideas; his thought is made implicit in the structure of the plays, and if his most telling strokes are considered only as examples of theatrical virtuosity, naturally the thought disappears.

Electra.—Two scenes from the *Electra* illustrate the fusion of his thought with his art. It is easy to dismiss the messenger scene as being no more than a clever piece of stagecraft. Clytemnestra has been terrified by a dream portending that her son Orestes will return from exile to avenge his father upon her and her accomplice Aegisthus and to reverse their usurpation. She comes out from the palace; she offers prayer and sacrifice to Apollo that he will avert the omen of the dream, divert it upon her enemies (meaning Orestes and Electra her daughter), frustrate them and preserve for her what her murder and adultery have won. She has only just finished the sacred rite when there enters, unrecognized, Orestes' old servant with a story—prearranged by Orestes—that Orestes is dead: it is designed to throw Agamemnon's murderers off their guard. The story of his supposed death in a chariot race at Delphi is itself a brilliant narrative; the situation enhances it, for it is being told to the mother who finds her own deliverance through the death of her son, and to the sister who finds in it the ruin of all her life; the messenger's preoccupation is so to deceive Clytemnestra that he may be invited into the palace to make ready for Orestes' coming. But this is by no means all, for an audience that believed in Sophocles' gods—being in any case assured already, through the chorus, that Zeus will bring the avenger home to triumph, and that retribution follows crime—would see in the arrival of the messenger, directly after the blasphemous prayer, the god's devastating answer to it. So it is too with the *coup de théâtre* in which the play ends. Clytemnestra has summoned Aegisthus from the countryside to hear the glad news. He enters, arrogant, secure at last from any threat of vengeance. He orders those who have brought the body to bring it out and display it publicly. "Here lies one," he says, "struck down by the anger of the gods." He is right; he draws back the shroud, and finds himself looking at the face of his dead wife. Whereupon Orestes drives him in to die on the spot where he had murdered Agamemnon. So do the gods work; crime breeds its own recoil.

It is the interfusion of divine and human action that gives to Sophocles' character drawing its deep significance. Electra is seen, for example, passing through the whole range of human emotion—from passionate love to cruel hatred, from numb despair to wild joy; the audience sees, in some detail, how her daily life with the murderers has entered like iron into her soul; she can live for nothing but vengeance and liberty. Orestes too, living on charity in exile, needs, and receives, no divine prompting: he asks Apollo not whether to do it but how to do it; however the god, though he approves, does not help. Sophocles is showing not that the gods from afar intervene to punish crime, but that the retribution comes in the natural order of things.

Antigone and Trachiniae.—In the *Antigone* the prophet warns Creon that all the gods are angry at what he has done and that their Avengers are lying in wait for him. What the prophet threatens comes to pass, not through "divine intervention" but through the instinctive reactions against Creon of Antigone, Haemon his son and Eurydice his wife. It is not the personal conflict between Antigone and Creon, great though it is, that is the deepest conflict in the play, but the conflict between Creon and the gods. He, for what he thought good reasons, ordained that the body of Antigone's traitor brother should not receive burial, the last tribute that humanity pays to humanity, but should be eaten by animals; Antigone rising in total rebellion, obeying all her instincts of love, loyalty and humanity, is indeed obeying "the unwritten and unchanging laws of the gods"; Creon is defying them, and they crush him. Individual characters and personal conflicts are in no way diminished or obscured by being set in this universal framework; on the contrary, they preserve to the full their own particular sharpness, and receive the added significance of being made universals.

The *Trachiniae* becomes unintelligible in structure only when we reduce it (perhaps under the influence of Aristotle) to personal dimensions. Sophocles makes it quite clear what the scope of the play is. At the beginning, Heracles' patient and understanding wife is distracted with anxiety at the ominously long absence of her husband. Reassuring her, the chorus observes that in human life joy and sorrow alternate like day and night; they follow the same universal rhythm. Therefore, having known little but sorrow, she may now expect joy. Moreover, Heracles is a son of Zeus, and Zeus does not neglect his offspring. But at the end of the play, she is dead and he is dying—ravaged by the "shirt of Nessus" that she had innocently sent him, to charm back his love—and their son Hyllus cries out upon the cruelty of the gods, who have brought this to pass. But the play has made it clear why, in this case, the universal rhythm broke down: to get a young girl for his mistress, in utter disregard of his wife, Heracles has destroyed a city, killing all the men and enslaving the women. This *hubris* is followed by a second, when he sends the girl to live in Deianeira's house. Deianeira was certainly simple-minded in trusting to a supposed love charm given her by an enemy of Heracles; Sophocles' point however is that ignorance is an inescapable part of the human condition: later, he makes Hyllus curse his mother, in his ignorance, for a vindictive murderess, and then repent bitterly when he learns the truth. Life at its best is a precarious affair, but it was the reckless violence of Heracles, acting within this precarious framework, not the cruelty of the gods, that brought all down in ruin.

Ajax and Oedipus Rex.—The hero of the *Ajax* is like Shakespeare's Coriolanus: he is a magnificent fighting man, a great bulwark of the commonwealth, who yet ruins all through an insensate pride that drives him into treachery and crime, and so to suicide. If this were all, there would be no need of the final scenes; but in these, too, Sophocles draws attention to the human condition and the demands it makes. Twice already has the arrogance of Ajax affronted the gods; now, when the prize of valour has been adjudged not to himself but to his enemy Odysseus, his instant response is to murder the judges, his commanders. In this he is frustrated by Athena, who visits him with an attack of madness, so that he kills sheep instead. Athena—no gracious Madonna—points to the humiliated Ajax and invites Odysseus to exult over him: "You see how strong the gods are!" But he, unlike Menelaus later, will do no such thing: "I pity him in his ruin, for I see that Man is nothing but an empty shadow." "Therefore," says Athena, "shun pride; it is the prudent that the gods cherish." Nemesis comes to the great Ajax when he falls on his own sword: he has lacked understanding of the way in which Man must live. So also do the two kings, when they order that his body shall be flung out to the animals—Menelaus, out of mean vindictiveness; Agamemnon, to vindicate discipline. But this is no way in which man should treat man. Once more it is Odysseus who shows understanding: no man, he says to Agamemnon, is always loyal and good; we must remember benefits and forget injuries. Any man may some time stand in need of forgiveness. Death is the common lot, and it must be respected. Agamemnon yields, but only as a favour to Odysseus, and Ajax's brother will not allow

Odysseus to have any share in the funeral rite, fearing the anger of Ajax's spirit; so that Odysseus reluctantly departs, the only one in the play who understands the human condition and shows true reverence towards the gods.

In the *Oedipus Rex,* the most famous of the seven plays, the scene of discovery, between Oedipus and the two shepherds—only 86 verses long—is surely among the most tense in all dramatic literature. The play is sometimes described as a tragedy of blind, inexorable Fate before which human efforts, even human virtue, are of no avail. This interpretation, would, however, contradict the whole trend of Sophocles' work, and in particular the third ode in this play. Sophocles insists always on the necessity for reverence, purity, moderation—though, being a tragic poet, he never pretends that these virtues will ensure security. One of the many tragic moments in the play is when Jocasta, jubilant before she learns the truth, proclaims that since life is random it is best to abandon principle and live from hand to mouth. The unifying thought in the play seems to be that since not even the greatest and most intelligent of us can control things, we should avoid the self-confidence that disregards religious restraints and leads straight to disaster.

Philoctetes and Oedipus Coloneus.—The *Philoctetes* concerns Neoptolemus the honourable but inexperienced son of Achilles who, on a clever plea of harsh political necessity, reluctantly undertakes a repulsive crime, only to find that it is much more repulsive than he had foreseen, and also completely useless. The shifting relationship between him and his intended victim and Odysseus (who in this play is a plausible rogue) is presented with the utmost delicacy and vividness; also, in the background is the suggestion that the Greek commanders themselves, by their past inhumanity toward Philoctetes, have caused their present frustration, from which they are trying to escape by even worse inhumanity.

The last play, *Oedipus Coloneus,* is also the most imaginative, and is surpassed by none in the power and beauty of its poetry. Oedipus, now old, blind, an outcast, his very name a source of horror, is summoned by the god to his final resting place at Colonus, and becomes, in his death, a mysterious source of defense to the land that has given him refuge.

The Satyr Play.—The *Ichneutae* is based on two stories about the miraculous birth of the god Hermes: that the infant, growing to maturity in a few days, stole cattle from Apollo, baffling discovery by reversing the animals' hoof marks, and that he invented the lyre by fitting strings to a tortoise shell. In this incompletely recovered play the investigators are the chorus of Satyrs, who are looking for the cattle; they are amusingly dumbfounded at the sound of the new instrument. Enough of the play survives to give an impression of its style: it is a genial, uncomplicated travesty of the tragic manner; the antics of the chorus were apparently the chief source of fun. It escapes from the intensity of tragedy into a world in which myth is taken quite literally, for the sake of relaxation and amusement—a very suitable conclusion to a day in the theatre, most of which had been occupied by the strenuousness of three tragedies.

See also references under "Sophocles" in the Index.

Bibliography.—On the manuscripts the standard work is A. Turyn, *Studies in the Manuscript Tradition of the Tragedies of Sophocles* (1952). The text of the seven plays was edited by R. C. Jebb (1897) and by A. C. Pearson, Oxford classical texts (1924). Of the commentaries, the best and fullest are those of R. C. Jebb, 7 vol. (1889–1914), each giving with the text an introduction, commentary and translation, supplemented by A. C. Pearson's three similar volumes on the fragments (1917). Jebb's translations, though archaic in style, are faithful. The Budé text is edited, with introductions, by A. Dain, with French translation by P. Mazon (1950–). *Oedipus Tyrannus* has been edited by J. T. Sheppard with explanation and translation (1920). *See* also J. C. Kamerbeek, *Plays of Sophocles* (1953–1959).

SOPHONIAS, PROPHECY OF: *see* Zephaniah, Book of.

SOPHRON of Syracuse (fl. *c.* 430 b.c.), was the author of rhythmical prose mimes in the Doric dialect. Although the mimes survive mostly in fragments of only a few words, it can be seen from their titles, *e.g., The Tunny-fisher, The Sempstress,* etc., that they depicted scenes from daily life. One longer fragment deals with a magical ceremony. Plato thought highly of Sophron, who had some influence on Theocritus and also on Herodas.

For fragments *see* G. Kaibel (ed.), *Comicorum Graecorum fragmenta* pp. 152–181 (1899); and for the longer fragment *see* D. L. Page (ed.), *Greek Literary Papyri,* "Loeb Series," 2nd ed., vol. 1, pp. 328–331 (1942). (E. A. B.)

SOPOT, a town of northern Poland in Gdansk (Danzig) *wojewodstwo* (province), and a popular seaside and health resort. Pop. (1960) 44,000. It stands on the wooded slopes of an elevation cut by ravines. The town is a well-developed cultural centre, with three theatres, and higher schools of economics and music. It has good road and rail communications with Gdynia and with Danzig and the larger towns to the south. It is also a port for coastal shipping. Sopot is mentioned in historical documents of the late 13th century, and was a favourite resort of the inhabitants of Danzig during the 17th and 18th centuries. Its modern development as a resort dates from 1823; it acquired town rights in 1902. Sopot was incorporated within the boundaries of the Free City of Danzig by the Treaty of Versailles in 1919; it passed to Poland in 1945. (K. M. Wi.)

SOPRANO, in music, the highest human voice. The term is generally applied only to the highest of the three types of voice of female singers (and of the 17th- and 18th-century male *castrati; see* Castrato; Eunuch), "treble" usually being used for a boy's voice of corresponding compass. *See* also Voice.

SOPRON (German Ödenburg), a town in Györ-Sopron *megye* (county), Hungary, lies in a salient projecting into the Burgenland (*q.v.*), Austria, 140 mi. (225 km.) W of Budapest by rail. Pop. (1960) 41,246 (mun.). Known to the Celts as Scarbantia (or Scarabantia), and then a Roman municipium, it later absorbed much German settlement. The town spread from a nucleus of medieval buildings, including notably the late medieval Benedictine church and the Church of St. Michael. Sopron and its district were especially associated in Hungarian history with the Esterházy and Széchenyi families. After World War I the Burgenland was allotted to Austria, but Sopron voted (1921) to remain in Hungary. This created economic problems, for Sopron's trade went mainly toward Vienna, and during the 19th century it had become a nodal point of rail and road traffic. The town has grown little in the 20th century but has some industries including fruit preserving, sugar refining, and the production of cotton goods. Franz Liszt was born at Raiding nearby. (H. G. S.)

SOPWITH, SIR THOMAS OCTAVE MURDOCH (1888–), British aircraft designer and yachtsman, was born in London, Jan. 18, 1888. He taught himself to fly in 1910 and in that year won the de Forest prize for the longest flight to the continent. In 1912 he founded Sopwith Aviation Co., Ltd., at Kingston-upon-Thames and, flying a Blériot monoplane, won the first aerial Derby. In 1914 he designed and built the seaplane that won the Schneider trophy. During World War I his firm produced many military aircraft, including the "Pup," "Camel," "1½-strutter," and "triplane." Sopwith was chairman of the Society of British Aircraft Constructors, 1925–27. In 1935 he became chairman of the Hawker Siddeley Group, Ltd., which during World War II built the Hurricane fighter and the Lancaster bomber. They also built the first British jet aircraft, the Gloster E 28/39, powered by the Whittle engine (*see* Whittle, Sir Frank). Between the wars Sopwith raced such yachts as "Endeavour" and "Endeavour II." (D. Cr.)

SORANUS (fl. 2nd century a.d.), Greek physician born at Ephesus, was the chief representative of the school of physicians known as "methodists." He practised in Alexandria and Rome. Two treatises by him are extant: *On Fractures* (in J. L. Ideler,

Physici et medici minores, i, 1841) and *On Midwifery and the Diseases of Women* (first printed in 1838). The latter was the source of many works on obstetrics; the book also contains a chapter on the care and feeding of infants. Of Soranus' most important work, *On Acute and Chronic Diseases*, only a few fragments in Greek remain, but there exists a complete 5th-century Latin translation by Caelius Aurelianus.

SORANUS, an underworld deity worshiped in antiquity on Mt. Soracte, in Etruria north of Rome. Traditionally the Hirpini (*q.v.*) got their name from the fact that once as they worshiped Soranus, wolves (*hirpi*) carried off the sacrificial entrails (Servius, *ad Aeneid*, xi, 785). As priests the *hirpi* (or *hirpini*) *Sorani* celebrated a rite in which they marched over burning coals barefooted (Pliny, *Natural History*, vii, 2, 19). Soranus was identified with Dis and Apollo (*q.v.*) and had a female partner, Feronia.

(R. B. Ld.)

SORBONNE: *see* Paris, University of.

SORBY, HENRY CLIFTON (1826–1908), English pioneer petrographer and microscopist, was born at Woodbourne, near Sheffield, on May 10, 1826. His first paper, on sulfur and phosphorus in agricultural crops, was published in 1847. An early paper dealing with the origin of valleys in Yorkshire was followed by others on the physical geography of geological periods, rock denudation and deposition and the formation of river terraces.

In 1849 Sorby began to prepare thin sections of rocks for study under the microscope, thus demonstrating the value of petrography, the descriptive branch of petrology (*q.v.*). In 1857 he proved that slaty cleavage was produced by lateral pressure which caused the rearrangement of particles in shaly rocks. His memoir "On the Microscopical Structure of Crystals," published in 1858 in the *Quarterly Journal of the Geological Society of London*, made a strong plea for the adoption of microscopic methods in geology and illustrated their value.

In 1865 Sorby announced a new type of spectrum microscope to be used in study of organic pigments, and especially in determination of minute bloodstains. He studied the metallography of iron and steel, concluding that the latter was a crystallized igneous rock, and did related work of industrial value. His later geologic studies dealt with, among other subjects, the origin of limestones and other stratified rocks, and weathering. His publications in these various fields number 240. He died in Sheffield on March 9, 1908.

(C. L. Fe.; M. A. F.)

SORDELLO (*c.* 1200–before 1269), the most renowned of Italian troubadours, was born, *c.* 1200, at Goito, near Mantua, and became famous in 1224, when at the court of Richard of Bonifazio, at Verona, he abducted his master's wife, Cunizza, at the instigation of her brother. After this act (which was primarily political in purpose, whether or not it was rewarded with Cunizza's love), he went to Treviso, married Otta di Strasso and, pursued by the hatred of several families, crossed the Alps. He traveled, in the way of a troubadour, through Spain and southern France, sang the praises of many ladies, and, *c.* 1237, settled at the court of Raymond Berengar IV of Provence. After Raymond Berengar's death in 1245 he remained in Provence, and later became a companion of Charles of Anjou, with whom he returned to his native country in 1265 when the latter became Charles I of Naples and Sicily. In 1266 he was a prisoner in Naples. He died sometime before 1269, probably in the Angevin Kingdom of Naples.

Sordello, who is made the type of patriotic pride in Dante's *Purgatorio*, is also the subject of a poem by Robert Browning. He left 1,325 lines of a didactic poem *L'Ensenhamen d'onor* and 42 lyrical pieces, including 12 *canzos*, 6 *tensons* and *partimens*, and 7 *sirventès*, mostly love songs and satirical pieces. (*See* Troubadours: *Literary Forms*.) His *planh*, or lament, on the death of his patron Blacatz (Blacas; 1237), in which he invites all Christian princes to feed on the heart of the hero, is one of the masterpieces of Provençal poetry.

Bibliography.—C. de Lollis, *Vita e poesie di Sordello di Goito* (1896); E. Benson, *Sordello and Cunizza* (1903); *Sordello: le poesie*, new critical edition by M. Boni (1954).

(A. A. F. B.)

SOREL, ALBERT (1842–1906), French historian, noted for his study of diplomatic history, whose works greatly influenced historical research on the Revolution of 1789. Born at Honfleur, Normandy, on Aug. 13, 1842, he entered the Ministry of Foreign Affairs in 1866 and was attached to the diplomatic delegation of the government at Tours during the Franco-German War (1870–71). In 1872 he helped to found the École Libre des Sciences Politiques, where he taught until his death. Nominated general secretary of the Sénat in 1875, he devoted most of his time to the study of history. In 1889 he was elected to the Académie des Sciences Morales et Politiques and, in 1894, to the Académie Française. He died in Paris on June 29, 1906.

Sorel was the author of many books, notably *L'Histoire diplomatique de la guerre franco-allemande* (1875), *La Question d'Orient au XVIII^e siècle* (1878), *Montesquieu* (1887), *Madame de Staël* (1891), *Bonaparte et Hoche* (1896), and especially *L'Europe et la Révolution française*, eight volumes (1885–1904), in which he demonstrates that the Revolution continued the traditional policy of establishing and defending "natural frontiers," especially those on the left bank of the Rhine. France, in his view, encountered an equally traditional opposition from its neighbours, particularly from England, and was finally beaten by those to whom it claimed to have brought liberty and independence.

See G. Picot, *Albert Sorel* (1907); F. Hess, *Albert Sorel als Historiker* (1932).

(J. A.-S.)

SOREL, CHARLES, Sieur de Souvigny (1602–1674), French writer, author of *Histoire comique de Francion* (1623), a picaresque novel of the road in Burgundy and Paris, remarkable chiefly for its sense of life and vigour of language; it went through 30 editions before the end of the century. He also wrote *Le Berger extravagant* (1627), *Polyandre* (1648) and many shorter satires and scholarly and religious works, including one of the first histories of French literature, *La Bibliothèque Françoise* (1664).

Sorel was born in Paris. Guy Patin in his letters described him as a fat little man with a sharp nose, leading a quiet bachelor's life with his sister, planning more works than his health would allow him to write. His chief glory is to have inspired more than one scene of Molière. He died on March 7, 1674. (W. G. Me.)

SOREL, GEORGES (1847–1922), French social philosopher, an unorthodox commentator on Marxism, and the exponent of a doctrine of violence that has been misrepresented as one of the foundations of totalitarianism. He was born at Cherbourg on Nov. 2, 1847. He received scientific training, served as a government civil engineer until 1892, and always retained a lively interest in the philosophies of science and technology, exemplified even in such works as *L'Ancienne et la Nouvelle Métaphysique* (1894), *Les Préoccupations métaphysiques des physiciens modernes* (1905), and *De l'utilité du pragmatisme* (1917). In these he expounded a relativist and pluralist conception of knowledge, but his thought was never irrationalist.

Sorel in retirement devoted himself to writing articles for various French and Italian periodicals, but his writings were unsystematic and of uneven quality. Originally he had been a liberal conservative, as is evident from his *Procès de Socrate* (1889); but in 1893 he discovered Marxism and began writing the analytical critiques that constitute his most original and valuable achievement. He strongly opposed Karl Kautsky's determinist simplifications and not only showed himself sympathetic to Eduard Bernstein's revisionism but also interpreted Marxism as a philosophy of freedom and action.

After being passionately Dreyfusard in 1897 (*see* Dreyfus, Alfred), Sorel became disgusted with certain aspects of the political exploitation of "the Affair." By 1902 his thought had grown most extreme, and he enthusiastically supported revolutionary syndicalism, a movement with anarchist leanings stressing the spontaneity of the class struggle. His most famous work, *Réflexions sur la violence* (1908; Eng. trans. 1914 and 1950 [*Reflexions on Violence*]), was a philosophic commentary partly inspired by Henri Bergson. In it he developed his notions of "myth" (modeled on the syndicalist vision of a general strike) and of "violence." Violence for Sorel was the revolutionary denial of the existing order; but in describing its creative historical role he opposed it to "force," that is, to the state's power of coercion, the abuse of which he consistently denounced.

After 1909 Sorel's thought took a less certain direction. Feeling obliged to revise his revolutionary syndicalism, he adhered, not without embarrassment and hesitation, to the monarchist movement Action Française. Next, regarding World War I as a betrayal, he declared himself for Bolshevism in his *Plaidoyer pour Lénine* (1919)—with the more enthusiasm because he thought it a lost cause. He died at Boulogne-sur-Seine on Aug. 28, 1922.

Sorel is sometimes held to have inspired Communist and Fascist dictatorship. Yet he had no influence at all on Lenin, who mentions him only once, with contempt, for Sorel denounced everything that might subject socialist action to control by party leaders. Benito Mussolini frequently professed himself to be a disciple of Sorel, whose theories of "myth" and of "violence" he took to glorify the blind motivation of the mob and to justify mere physical brutality—distortions which Sorel explicitly condemned

See R. Humphrey, *Georges Sorel, Prophet Without Honor* (1951). (G. Gy.)

SORGHUM, a cereal, forage, and sirup crop plant grown in many countries and known botanically as *Sorghum vulgare*. It probably originated in Africa. The types grown for grain (grain sorghum) are called by various names, including durra, milo, shallu, kafir corn, Egyptian corn, great millet or Indian millet. On the subcontinent of India it is known as jowar, cholum, or jonna; in the West Indies as petit mil or Guinea corn; and in China and Manchuria as kaoliang. Sorghum is a strong grass, growing to a height of from 2 to 8 ft. or even 16 ft. The stalks and leaves are coated with a white waxy bloom. The pith in the stalks of certain varieties is juicy and sweet. The leaves are sheathing, solitary, and about 2 in. broad and 2½ ft. in length; the panicles or flower clusters are loose, contracted, or dense. Self-pollination of the flowers is common but considerable cross-pollination occurs. The grains may be either free or retained in the hulls after threshing. Many varieties are awned. The seeds are ellipsoid, rounded, or flattened and of varied sizes somewhat smaller than wheat grains. The seeds may be white, yellow, red, or brown. The hulls are mostly straw-coloured, red, brown, or black.

W. H. HODGE

SORGHUM (S. VULGARE)

Sorghum is the leading cereal grain in Africa and is important also in the United States, India, Pakistan, north China, and Manchuria. It is grown to some extent in the U.S.S.R., Iran, Arabia, Argentina, Australia, and southern Europe, as well as in other regions. It is best adapted to warm conditions and is very resistant to drought and heat. Hundreds of varieties are grown. The grain is similar in composition to that of corn (maize) except in being higher in protein and lower in fat. It replaces corn as a feed grain in hot, dry regions. For food it usually is ground into a meal and made into porridge, bread, or cakes. Natives of southern Africa refer to the product as "mealies." Whole grains sometimes are popped or puffed. The grain also is used in making an edible oil, starch, dextrose, paste, and alcoholic beverages. The stalks provide fodder and building materials. The sweet sorghums (sorgos) are grown chiefly in the U.S. and southern Africa for forage or for sirup manufacture. The sweet stalks are chewed by peoples of various countries. The broomcorn plant, belonging also to the species *S. vulgare,* is similar to other sorghums in adaptation and many characteristics; it is used in making brooms. (J. H. Mn.)

SORIA, a city and province of north-central Spain. The city, the provincial capital, lies on the Duero (Douro) River, 115 mi. (185 km.) NE of Madrid. Pop. (1960) 19,301 (mun.). Restored after the Moorish invasion, medieval Soria was ruled by the unique Doce Linajes (12 noble families who governed in turn). The churches of Santo Domingo and San Nicolás, the collegiate church of San Pedro, the cloister of the convent of San Juan de Duero, and other ecclesiastical buildings are fine specimens of Romanesque work. Near the Duero are the ruined citadel and 13th-century walls. The Numantine Museum houses important relics excavated from nearby Numantia (*q.v.*). Commercial activities include food processing (flour, dairy products, meat packing, wine), sawmilling, and the manufacture of cement, tiles, and soap. There are road and rail communications with Madrid, Saragossa, Burgos, and Pamplona.

Soria Province was formed in 1833 out of Old Castile. Area 3,972 sq mi. (10,287 sq km.); pop. (1960) 147,052. It is a bleak, austere region, bounded on three sides by mountains, and has a cold, dry climate. Most of the province is watered by the Duero and its affluents and crops are grown in irrigated areas. There are forests of pine, oak, and beech, and large tracts of grazing land (mostly for sheep). (J. A. P.-R. y G.-S.)

SORIN, EDWARD FREDERICK (1814–1893), French-U.S. Roman Catholic priest and educator, founder and first president of the University of Notre Dame, was born at Ahuillé, near Laval, France, on Feb. 6, 1814. Ordained priest in 1838, he joined in 1840 the Congregation of Holy Cross, a group of priests and brothers organized at Le Mans by Abbé Basil Antoine Moreau.

At the invitation of Bishop Celestine Hailandière of Vincennes, Ind., Sorin and six brothers went to Vincennes in 1841, at first settling at St. Peter's in Daviess County. In 1842 Hailandière offered Sorin land near South Bend, in St. Joseph County, where Father Stephen Theodore Badin had formerly conducted the mission Sainte Marie des Lacs. Sorin arrived there on Nov. 26, and in 1844 he obtained from the general assembly of Indiana a charter for the University of Notre Dame. He was president of the university until 1865, was provincial superior of his community in the United States until 1868, and was from then until his death, on Oct. 31, 1893, the superior general.

In 1843 Sorin established at Bertrand, Mich., near Notre Dame, a community of French Sisters of Holy Cross, and in 1854 secured for them the site adjacent to Notre Dame on which St. Mary's College was founded. He was instrumental in bringing to the Sisters of Holy Cross Mother Angela (Eliza Maria Gillespie), who guided the community for nearly 30 years. In 1865 Sorin began publishing *Ave Maria* magazine. (T. T. McA.)

SORITES. In traditional logic, a chain of successive categorical syllogisms in the first figure (*i.e.*, where the middle term is subject of the major premiss and predicate of the minor premiss; *see* Logic, History of: *Ancient Logic: Aristotle*) may be so related that either the conclusion of each except the last is the minor premiss of the next, or the conclusion of each except the last is the major premiss of the next. If then the intermediate conclusions are suppressed (*i.e.*, the conclusions of all the successive syllogisms except the last), and only the remaining premisses and the final conclusion are stated, the resulting argument is a valid inference from the stated premisses, which may be considered independently of its analysis into syllogisms, and which is called a sorites. In the case of the first alternative we have the so-called Aristotelian sorites, and in that of the second the Goclenian sorites (enunciated by the German logician Rudolph Goclenius, 1598). Considered as independent inferences, the Aristotelian and Goclenian are identical, except for the matter of the order in which the premisses are stated. But the Aristotelian and Goclenian analyses of the sorites into syllogisms are different.

An example, taken from Lewis Carroll, is the following. The premisses are: (1) No one takes in [subscribes to] the *Times*, unless he is well-educated; (2) No hedgehogs can read; (3) Those who cannot read are not well-educated. The expected conclusion is: (5) No hedgehog takes in the *Times*. To analyze this into syllogisms, we restate the premisses, with obversion of (2) and (3), as follows: (1a) None who are not well-educated take in the *Times*; (2a) All hedgehogs are unable to read; (3a) All who are unable to read are not well-educated. In the Goclenian analysis, the first syllogism has (1a) as major premiss, and (3a) as minor premiss, and hence the intermediate conclusion, (4) None who are unable to read take in the *Times*. Then the second syllogism has

(4) as major premiss and (2a) as minor premiss, hence (5) as final conclusion.

In a more complicated example there might be more than three premisses. In general, there may be $n + 1$ premisses, and analysis then yields a chain of n successive syllogisms.

See Lewis Carroll (Charles Lutwidge Dodgson), *Symbolic Logic*, 4th ed. (1897, reprinted 1958); J. N. Keynes, *Studies and Exercises in Formal Logic* (1884 and later editions to 1906). (Ao. C.)

SORØ, an *amt* (county) in southwest Sjælland (Zealand), Denmark. Area 571 sq.mi. (1,479 sq.km.). Pop. (1960) 129,580. This prosperous farming region with its fertile clay loams is drained by the Tude River in the west and by part of the Sus River system in the east. The principal towns are Slagelse (pop. [1960] 20,562), Ringsted (9,694), and Sorø (5,494), all inland, the important ferry port of Korsør (14,276) and the minor port of Skælskør (2,889). The administrative centre is Sorø. (Ha. T.)

SOROLLA Y BASTIDA, JOAQUIN (1863–1923), Spanish painter, whose style was a conservative variant of Impressionism, was born at Valencia on Feb. 27, 1863, and studied at the academy there, in Italy, and in Paris, where he especially interested himself in the works of J. Bastien-Lepage and A. von Menzel; he was also influenced by the north European realists, particularly A. Zorn. His early paintings were of history and social realism (one of the latter kind, "Otra Margarita," 1892, being his earliest success), but he later became well known for brightly lit scenes with Valencian peasants and fisherfolk and children playing in the surf, his style after about 1903–04 becoming impressionistic and summary, with heavily impasted pigments. Between 1910 and 1920 he painted portraits of Spanish writers and a "Panorama of the Forty-nine Provinces of Spain" for the Hispanic Society of America. Sorolla died in Madrid on Aug. 10, 1923.

SORORATE, a term introduced by Sir James George Frazer to designate all marriages with a wife's sister, whether in the lifetime of the first wife or after her death. In his view, generally accepted in the 1960s, it is complementary to the custom of the levirate (*q.v.*). The concept appears in the work of Sir Edward Burnett Tylor where levirate and sororate figure as correlates of the postulate that matrimony is a bond between families rather than individuals. A. R. Radcliffe-Brown subsumed both institutions under the principle of the social equivalence of brothers and sisters, respectively. These relationship terms are to be understood in a classificatory sense; *i.e.*, a more remote relative of the same sex may serve as secondary mate instead of a blood sibling. Though related in principle, the levirate and sororate are not invariably associated, but they usually are, and appear to be the commonest of preferential secondary marriages. Either may be permissive rather than obligatory. The Maricopa (Arizona) traditionally insisted on a widow's marrying a husband's relative, whereas the replacement of a deceased wife by a kinswoman of hers was customary, but not compulsory.

Though successive and simultaneous marriage of two or more sisters falls under the same principle, some peoples (*e.g.*, the Kazakh) favour one, while tabooing the other practice. Hence it has become necessary to distinguish between sororal polygyny and sororate. The typical rule for the former is that the husband of the eldest girl in a family marries her juniors as they come of age; L. H. Morgan found this usage in at least 40 North American tribes during the 19th century; more recently Navaho men often were simultaneously married to two sisters, occasionally to three. Australian aborigines recognized the same preemptive claim, but in many tribes the husband contented himself with the two oldest girls, conveying his claims on their younger sisters to his junior brother. With remarkable unanimity aborigines explain sororal polygyny on the ground that sisters are unlikely to quarrel as co-wives.

The effect of both the sororate and sororal polygyny is to have children extend the term mother to the maternal aunt, but this terminological trait is more probably directly correlated with unilinear descent.

See also Marriage, Primitive.

Bibliography.—A. R. Radcliffe-Brown, *The Social Organisation of Australian Tribes* (1931); R. H. Lowie, *Social Organization* (1948); George P. Murdock, *Social Structure* (1949); H. G. Nutini, "Polygyny in a Tlaxcalan Community," *Ethnology*, vol. iv (April 1965).

(R. H. Lo.)

SORORITY, a social, professional or honorary organization of women, usually a secret society whose name consists of a series of Greek letters and which is connected with a college or university. *See* Fraternity and Sorority.

SORREL, any of several herbs, some weeds, of the genus *Rumex* of the buckwheat family (Polygonaceae), especially *R. acetosa*, the garden sorrel; *R. acetosella*, sheep sorrel; and *R. hastatulus*, heartwing sorrel. The leaves of garden sorrel are used as greens in soups, salads, and sauces. French sorrel, *R. scutatus*, is a hardy perennial, distributed throughout Europe.

Species of *Oxalis* (*q.v.*) are commonly called wood sorrel or lady's sorrel. The sourwood (*Oxydendrum arboreum*) is known as the sorrel tree, an attractive deciduous tree of the heath family, native to the southeastern United States; its leaves turn a brilliant scarlet in the autumn.

SORRENTO, a city of Campania and in Napoli Province, Italy, stands on a peninsula separating the Bay of Naples, which it faces, from the Gulf of Salerno, 17 mi. (27 km.) SSE of Naples. Pop. (1961) 12,531 (commune). The backbone of the peninsula is formed by the Monti Lattari, the highest of which, Monte Sant'Angelo, rises to 4,735 ft. (1,443 m.). The cathedral has a marble side portal of 1479, and the church of St. Francis of Assisi has a picturesque 14th-century cloister. The Museo Correale di Terranova contains an important collection of Campanian decorative art, medieval sculpture, paintings, and classical remains. Sorrento is the seat of an archbishop.

Sorrento is linked by a branch line to the main railway from Naples to Salerno, and by rail and road with Pompeii and Mt. Vesuvius; steamers ply to Naples and the islands of Ischia and Capri. The district produces oranges, lemons, and nuts.

The ancient Surrentum, Sorrento has been a summer and winter resort since Roman times because of its agreeable climate and situation. Many writers, artists, and musicians have stayed and worked there; the poet Torquato Tasso was born there in 1544.

SORSKI, NIL (1433–1508), Russian saint and mystic, the first Russian mystic to write about the contemplative life and to leave a guide to the spiritual path of self-perfection, and the first Russian to advocate methodically in his writings asceticism and renunciation of worldly possessions. He was born in Moscow in 1433, but little else is known of his early life. He was tonsured in the monastery of St. Cyril at Beloozero and was present at the first council against the Judaizers (1490; *see* Joseph, Saint, of Volokolamsk). He made a voyage to Constantinople and Mt. Athos, where he studied patristic writings and acquainted himself with Hesychasm (*q.v.*) and the external forms of Athonite monasticism. After his return he founded his own monastery (*skit*) on the Sora River (hence "Sorski") near Beloozero, a small community bound together more by common worship than by strict discipline. In 1503, at a council in Moscow, he allegedly spoke against monastic landownership and is consequently known by historians as the leader of the so-called nonpossessor party within the Russian church (*see* Monasticism). He died on May 7 (his feast day), 1508.

Writing of the monastic life, Nil recommended moderation in fasting, in discipline, and in church decoration, stressing always the need for mental rather than physical asceticism. His writings, most of which are derivative, include a statement on the external precepts for the running of his monastery; a monastic rule (*Ustav*) in which instruction is given on how to analyze and overcome the passions on the way of self-perfection; and several epistles, usually containing words of comfort for his spiritual children.

See F. von Lilienfeld, *Nil Sorskij und seine Schriften* (1963), which contains German trans. of Nil's works. (J. L. I. F.)

SORSOGON, the name of a municipality, provincial capital, and the southernmost province of Luzon, Philippines. Area of province, 793 sq.mi.; pop. (1960) 347,771. The province is bordered on the south by San Bernardino Strait and comprises largely volcanic cones with broad rich level areas between; the highest peak is Mt. Bulusan (5,118 ft.), a recently active cone. Rainfall

varies from 100 in. to more than 160 in., with no dry season and maximum fall in the winter. Rice, sweet potatoes, and cassava are the main food crops produced, but the province is best known as an abaca (Manila hemp) centre. Before World War II slightly over 40% of the cultivated area was devoted to abaca, but by the 1960s this area was halved. Coconuts continue to occupy a significant proportion of the farmed area. Sorsogon (pop. [1960] 35,542) is a trading town, processing station for abaca and copra, and port on the northeastern shore of Sorsogon Bay. (R. E. HE.)

SØR-TRØNDELAG, a *fylke* (county) of central Norway. Area 7,227 sq.mi. (18,718 sq.km.). Pop. (1960) 206,802. It contains valleys and uplands south of Trondheimsfjorden, extending eastward to the Swedish border, and coastal districts west of the fjord, with the large islands of Hitra and Frøya. In the eastern fjord areas agriculture and forestry are favoured by fertile soil, but in the valleys agriculture is limited by climate and relief. Pyrite occurs in the districts of Røros and Orkdal. Røros (pop. [1960] 2,904), 2,065 ft. (629 m.) above sea level, is an interesting old mining village founded in 1644. In the coastal districts soil is more scarce and the hills more barren. Fishing is an important subsidiary occupation to agriculture. There are manufacturing industries in and around Trondheim (*q.v.*), which, being the site of the greatest medieval cathedral in Scandinavia, is by tradition a regional centre for a much wider area than the county. (L. H. HG.)

SOSNOWIEC, a town of southern Poland in Katowice *wojewodztwo* (province), and part of the conurbation of the Upper Silesian industrial region, is situated on the Czarna Przemsza River, a tributary of the Vistula, 6 mi. ENE of Katowice. Pop. (1960) 131,654. The town is a railway junction. Most of the inhabitants are employed in industry; and there are three coal mines, a number of heavy industrial plants (iron foundries, smelting works, machinery), and glassware and textile factories. The town has a mining museum, the first of its kind in Poland. Sosnowiec developed from a village into a factory centre of the Polish kingdom *c.* 1877. Its development is associated with the construction of the Warsaw–Vienna railway line in 1858. It obtained town rights in 1902. (K. M. WI.)

SOTER, SAINT, pope from about 166 to about 175. He wrote to the church of Corinth and sent it aid. His letter is mentioned in the reply given by Dionysius, bishop of Corinth, and A. Harnack thought that it could be identified with the so-called Second Epistle of Clement (but *see* CLEMENTINE LITERATURE). St. Soter's feast day is April 22.

SOTHERN, EDWARD HUGH (1859–1933), U.S. actor, widely popular for his roles in romantic comedy and noted also as a Shakespearean actor, was born at New Orleans, La., on Dec. 6, 1859, the son of the English comedian Edward Askew Sothern. His first stage appearance was in a small part with his father's company at the Park Theatre in New York City in 1879. He toured England in 1882–83, became leading comedian in John McCullough's company in 1883, and under Daniel Frohman was leading man at the Lyceum Theatre in New York. He married Virginia Harned in 1896 and in 1899 formed his own company with her as his leading lady.

In 1900 Sothern appeared in the title role of *Hamlet*, in 1901 in that of *Richard Lovelace*, and in 1902–03 as Villon in *If I Were King*, three of his greatest roles. In 1904 he played opposite Julia Marlowe (*q.v.*) for the first time in *Romeo and Juliet* at Chicago, Ill. Thereafter, except for two years, 1907–09, they appeared together on the stage almost continuously until their retirement. They were married in 1911. Besides *Romeo and Juliet* they played together in *Much Ado About Nothing*, *Taming of the Shrew*, *Merchant of Venice*, *Twelfth Night*, and *Macbeth* and in *Jeanne d'Arc*, *John the Baptist*, *When Knighthood Was in Flower*, and *The Sunken Bell*. Sothern had a repertory of over 125 diverse parts, but his audiences liked him best as the dashing, romantic hero in such plays as *The Prisoner of Zenda*. He died on Oct. 28, 1933, in New York.

See his autobiography, *The Melancholy Tale of Me* (1916).

SOTHO, one of the main cultural and linguistic groupings of the high grasslands of southern Africa. These Bantu-speaking Negro people were estimated to number more than 2,979,000 in the 1960s. They are classified as the Transvaal or Northern Sotho (Pedi, Lovedu, and others); Western Sotho (Tswana [*q.v.*] tribes); and Southern Sotho of Lesotho, the Basuto or Suto (*q.v.*).

See also AFRICA: *Ethnography (Anthropology)*: *Southern Africa;* LESOTHO: *The People;* BOTSWANA: *The People;* SOUTH AFRICA, REPUBLIC OF: *The People.*

BIBLIOGRAPHY.—In addition to the bibliographies of articles cited, *see* I. Schapera, *The Bantu-Speaking Tribes of South Africa* (1937), *Government and Politics in Tribal Societies* (1956); P. Duncan, *Sotho Laws and Customs* (1960). (J. F. M. M.)

SOUL. Man's experience of his own "inwardness," including his thoughts, desires, and feelings, is a characteristic and determining feature of the human form of existence. Whatever the forms of inwardness and consciousness that may be ascribed to other biological organisms, the structure of human experience is characterized by a reflexive inwardness; its determining mark is self-consciousness rather than mere consciousness. A corollary of this self-awareness is the capacity to objectify and to experience oneself as a subject *vis-à-vis* objects. However, it is not only the outside world or his physical body and its spatially localized and publicly observable activities that are objects for man's subjectivity. Man's subjectivity itself—*i.e.*, his own inwardness—can be objectified, both imaginatively and conceptually, and corresponding nonphysical objective entities (soul, mind, psyche, spirit) posited. But the further we push the objectifying analysis of man's faculties, drives, desires, feelings, and all his other "inward parts" and processes, the more imperative becomes the question as to the nature of that ultimate subject, or essence of personality, which does all the objectifying.

The quest for this elusive subject inevitably leads to an infinite regress. To escape from this regress some have denied the notion of a discrete soul substance or transcendental personality and have maintained that the concepts of ego, soul, or self merely reify the awareness of certain processes. The task of a critical philosophy would therefore consist in dereifying and dematerializing these images and concepts.

On a less critical and less sophisticated level, however, man has always been impressed by his dimension of subjectivity and by the manifold variety of the manifestations of his inwardness. Hence it is not surprising that man should frequently have taken a multiple rather than a unified, or holistic, view of his nature. Body and mind dualism is perhaps the best-known expression, in Western philosophy and religion, of this notion of discrete entities, but it certainly is not the only or the most obvious system of division. There are many different types and kinds of inwardness or of nonbodily selfhood, and a variety of psychological functions and vital phenomena (dreams, sleep, death, etc.) may give rise to notions of multiple souls. Without committing ourselves to E. B. Tylor's views regarding the extension of the notion of soul, as derived from immediate human experience, to disincarnate beings (spirits, demons, gods) and the attribution of souls to inanimate things (animism; *q.v.*), we may, nevertheless, agree that his description covers at least part of the facts:

> It seems as though thinking men, as yet at a low level of culture, were deeply impressed by two groups of biological problems. In the first place, what is it that makes the difference between a living body and a dead one; what causes waking, sleep, trance, disease and death? In the second place, what are those human shapes which appear in dreams and visions? Looking at these two groups of phenomena, the ancient savage philosophers probably made . . . the obvious inference that every man has two things belonging to him, namely a life and a phantom (*Primitive Culture*, 5th ed., vol. i, p. 428; London, John Murray, 1913).

The connection of the soul with the principle of life is also brought out by the terminology associating soul with "breath"; the Gr. *psyche*, Lat. *anima*, Heb. *nefesh*, *neshama*, and probably Sansk. *ātman* are all so associated. Sleep is often considered as a kind of minor death. Thus according to the Koran (6:60–61) God takes the souls of men back at death as well as every night during sleep; in the latter case, however, the souls are returned again in the morning.

Tylor collected a large amount of evidence for the belief in

multiple souls. The Fiji islanders know of a dark spirit, which ultimately goes to the underworld; and a light spirit, which can be seen as a reflection in water. Belief in duality of souls is widespread among North American Indians; among the Algonkians one soul goes out in dreams while the other stays behind; at death one remains behind while the other proceeds to the land of the dead. Tylor also quotes examples of three- and fourfold divisions. C. Nimuendaju has described the psychological system of the South American Apapocuva, who ascribe the different human characteristics to the several plant and animal souls inhabiting man. The idea of a multiplicity or even hierarchy of life- and soul-principles is found in higher civilizations too; it may be seen in, for example, the *ba* and *ka* of the ancient Egyptians, the Gnostic *psyche* and *pneuma*, or the fivefold division of the Jewish Cabalists (*nefesh, ruah, neshamah, ḥayyah, yeḥidah*). The Tikopia of the Solomons, on the other hand, know of one soul only, the *mauri* or *ora*, which after death becomes an *atua* soul.

Traditional definitions of the soul have usually emphasized man's consciousness of his psychological and mental processes, and the term was generally taken to denote the principle of thought and action in man, or as that which thinks, wills, and feels, conceived as a perdurable entity and a subject of conscious spiritual experience. Modern psychology has added a further dimension by drawing attention also to unconscious faculties, mechanisms, and experiences. Great variety in terminology and in conceptual traditions makes it difficult to generalize, though it is possible, perhaps, to distinguish between the notion of the soul as (1) the whole man minus the body, and (2) a special substance or collection of several substances. In the former case it is the whole, though disincarnate, man that survives and, *e.g.*, goes to the land of the dead; in the latter case it is a specific soul substance that persists and returns to its heavenly home or, alternatively, haunts the living or is reincarnated.

Science and Psychology.—As a scientific concept, soul did not require specific justification as long as its legitimacy was taken as axiomatic and accepted on general philosophical grounds. The division of man into *soma* and *psyche*, or even of the whole of reality into *res extensa* and *res cogitans*, as by Descartes, presupposed the existence of mind as an independent principle. The dichotomy gave rise to serious philosophical and logical problems, however (*see* BODY AND MIND), which came to a head in the 17th century. One line of thought may be traced from Plato to Leibniz and to the subsequent idealistic and vitalistic philosophies, but it also includes Aristotle's concept of the soul as the form, or entelechy, of the body. Aristotle's teaching, however, also has affinities with the more positivistic and naturalistic views, since it holds the soul to be inseparable from the body and consequently permits of a behaviourist (functionalist or even epiphenomenalist) theory of mind.

This second line of thought, which leads to naturalism and empiricism, has its philosophical antecedents—as far as modern thought is concerned—in Locke, though more recent research would hardly subscribe to the view that the mind is merely a passive and purely receptive organ for ideas which enter via the sensory apparatus. Whatever the correct view about ideas, it seems certain that forms of experience and behaviour are to some extent "given" in the cortex and in the central nervous system. Neurophysiology, electroencephalography, brain surgery, psychiatry, and research into mental states under the influence of LSD and other psychopharmaca have shown the fruitfulness of the naturalistic approach while not necessarily excluding some notion of mind or psychic activity. In fact, radical scientific naturalism, or criticism of the Lockean type, simply evades certain issues (*e.g.*, human inwardness, or the experience of freedom) by declaring these "introspective" areas out of bounds for the scientist or scientific philosopher and turning them over to the "nonscientific" philosophers, who apply to them their methods of phenomenological and existential analysis.

Up to a point the quarrel is either a semantic or a methodological one, the latter bearing on the delimitation of the proper areas of meaningful scientific research. In point of fact, however, these methodological or semantic considerations spill over into philosophy and ideology. The question is not merely one of determining the relation of psychology to philosophy (viz., philosophical anthropology) or theology, but of defining the scope of psychology. Is it the study of the manifestations of the soul, or the measurement of behaviour, or something in between these extreme positions? Or are the terms soul and mind merely convenient shorthand, standing for the fact that we are aware of mental activities and processes? A conditioned reflex psychology of the Pavlovian type (*see* CONDITIONING), or a strict behaviourism (*q.v.*) as conceived by J. B. Watson can discard mind as an unnecessary hypothesis. More recently cybernetics (*q.v.*), with its self-directing and self-controlling machines, has been claimed to provide possible models for an understanding of man.

The naturalistic, reductionist, and, as it were, soulless psychology (psychology without *psyche*, as some have said) has provoked other psychologists to emphatic assertions of the "reality of the soul" (C. G. Jung). These assertions, though impressive as testimonies to a profound awareness of man's psychological dimensions, have so far exhibited little or no capacity to deal with the logical and methodological challenge of naturalism and have certainly failed to distinguish sufficiently between psychological and spiritual dimensions of existence. Philosophical anthropology, with its phenomenological and existential analyses of the human mode of being (M. Plessner, M. Scheler, M. Heidegger, A. Gehlen), tries to bring out more clearly the specific spiritual character of human existence without, however, necessarily reifying it into spirit or mind, let alone into soul or immortal soul substances.

Psychical Research and Parapsychology.—Curiously, the allegedly most scientific attempt to establish the reality of souls (or of spirit or mind) is, at the same time, the most unspiritual and crudely material. Spiritualism, psychical research, and to a considerable extent, also parapsychology or metapsychology claim to produce evidence of the manifestations of spirits (souls) in mediumistic trances, materialization phenomena, tablelifting or tapping, ouija-board writing, reincarnations. (*See* PARAPSYCHOLOGY; PSYCHICAL RESEARCH.) The nature of the findings, as well as their interpretation, is still doubtful; it seems clear from a logical point of view, however, that while certain parapsychological phenomena (*e.g.*, telepathy) could, if properly established, prove the operation of laws other than those traditionally recognized by the physical sciences, yet they would still be far from proving the existence of spirits or individual souls. Altogether the ideological bias of psychical research is evident from the openly admitted belief that its findings should save modern civilization from its materialism and reawaken it to an awareness of the reality of mind. Thus J. B. Rhine, whose parapsychology laboratory at Duke University was well known, has declared that if his studies established the existence of "discarnate spirit personalities" (man's "living spirit") then there would be "dramatic proof of spiritual realities in everyday life that Science had failed so far to find. The machine theory would be wrecked once and for all." In fact, "proof of survival would squelch forever the dreadful error of the materialistic view of man on which Communism and other gross misconceptions about humanity rest. On the other hand, certainty about it could revitalize religion [*sic*] and give to all human life a new dimension" (Rhine, in *The American Weekly*, Dec. 7, 1957, pp. 7 and 32).

Western Philosophy and Religion.—Reference has been made in the preceding paragraphs to some of the philosophical presuppositions and implications of the concept of soul. In the history of Western philosophy, ideas regarding the nature and essence of the soul derive partly from Plato and Aristotle and partly from religious traditions (themselves indebted to philosophy) and preoccupations. While Plato held the soul to be eternal and preexistent, hence also capable of reincarnation, Aristotle's more biologically oriented definition implies that the soul is inseparable from the body. In fact, if soul is the technical term for the specific "form" of an organism, then human organisms are not the only ones to be endowed with souls. The Aristotelian tradition thus distinguished between vegetative, animal, and rational souls. Whereas the animal soul (also in a human individual) is born and perishes with the body, mind, or intellect (Gr. *nous*), which

is unoriginated and imperishable, enters the soul-germ from outside and remains unaffected by the death of the body. The combination of *nous* with the animal soul constitutes the human personality. Aristotle distinguished a passive and an active soul. Only the latter is eternal, whereas in the former Aristotle evidently hoped to find the link connecting *nous* and the animal soul.

It is not quite clear how Aristotle conceived the personal survival of a disembodied *nous*. Later representatives of the Peripatetic School, such as Alexander (*q.v.*) of Aphrodisias (*c.* A.D. 200), and some medieval Arab and Jewish Aristotelians denied the immortality of the soul even more uncompromisingly and explained the active *nous* (Latin *intellectus agens*) as the divine spirit working upon the soul (*see* ARABIC PHILOSOPHY: *Philosophers;* JEWISH PHILOSOPHY: *Aristotelianism in Medieval Jewish Philosophy*). Man's original endowment therefore consists of the disposition to thought ("potential" intellect) only. Immortality has to be acquired; it depends on the degree of development of the potential intellect; *i.e.*, on the measure of "acquired intellect" realized under the influence of the divine mind.

Neoplatonism had absorbed Aristotelian elements, and it is not surprising therefore that for Plotinus (*q.v.*) *nous*, the first product of the highest Being (the One), should be above the soul. In fact, *nous* creates the world soul, which in its turn creates and comprehends a plurality of particular souls. The Neoplatonic notion of an impersonal *anima mundi* has obvious pantheistic affinities (*see* PANTHEISM), while the idea of a return of man's particular soul to its original abode in the higher All Soul has definite religious qualities. To the extent that the return of the soul to its celestial or supramundane abode is conceived as a union (or reunion) with the godhead, Neoplatonism also has affinities with mysticism. Indeed, most systems of mysticism presuppose, by implication or by explicit teaching, specific psychologico-philosophical doctrines regarding the nature of the soul.

The Stoics did not teach immortality; for them the soul consisted of matter, though matter of the purest and noblest kind, part of the divine fire substance which descended from the ether into the bodies of men.

Western Christianity was influenced by the Neoplatonic tradition in its Latin form (St. Augustine) rather than in its pagan (Plotinus) or Greek Christian (pseudo-Dionysius) forms. When Aristotelianism penetrated the Schools, it cost St. Thomas Aquinas and others considerable effort to combine this teaching with the Christian belief in a created soul and in individual immortality. A radical distinction was also made between the "essence of the soul," in which the workings of divine grace take place, and the "faculties of the soul," with which psychology deals. The substance or essence of the soul (also *fundus animae*) is hidden, and only its actions through its faculties are manifest and phenomenally accessible.

Eastern Philosophy and Religion.—Just as in Western philosophy there is no agreement about the exact connotations of such terms as soul, spirit, or mind, Indian psychology too has a variety of terms which, though not synonymous, refer to the immaterial part of the individual: *jīva, citta, mano, vijñāna, ātman.* Generally speaking the *ātman* is considered, at least from the Upanishads on, as the essence or "self" of the individual and as that which underlies his consciousness, survives his death, and constitutes the continuity of the self in the cycle of transmigrations. According to the dominant schools of thought, *ātman* as the inner essence of the human personality is identical with the *brahman*, the "world soul"—the Absolute and the divine ground of all being. While this necessarily brief and superficial summary neglects the great variety of doctrines held by the divergent schools, it may nevertheless suffice to indicate the main trend of Indian thought on the subject and to give the background for the general belief in reincarnation (*see* below) which is assumed by all the religious systems of India. (*See* further INDIAN PHILOSOPHY.)

The Buddhist scriptures deny the existence of an *ātman* (Pali *attā*), and the doctrine of nonself (Sansk. *an-ātman*, Pali *an-attā*) is generally admitted to be one of the chief tenets of Buddhism. Disregarding both the problem of the origin of this doctrine and the question whether the Buddha himself engaged in explicit polemics against the traditional Upanishadic notion of *ātman*, it may suffice here to say that Buddhism regards the human individual as an agglomeration of five *skandhas* ("heaps" of elements). Insight achieved through meditation reveals the illusory character of the self. To assume the existence of a self is merely to reify as a substance the fact that there are mental processes. In this respect Buddhist psychology merely says, in its own fashion, what Locke or Hume or Gilbert Ryle have said in the terminology of European critical philosophy. Where Buddhism goes further is in preaching the necessity of this meditative insight as an indispensable condition for salvation. However, since Buddhism, while denying an individual self or *ātman* yet shares the general Indian belief in transmigration, the problem inevitably arises as to what exactly it is that survives to be reincarnated, that suffers transmigration, and that seeks release in nirvana (*q.v.*) from the wheel of *samsara.* It may be mentioned in passing that some Hindu apologists (*e.g.*, A. K. Coomaraswamy, *Buddha and the Gospel of Buddhism*, 1916) claim that the Buddha missed the basic Hindu teaching, according to which it is precisely not the *ātman* but a kind of "soul or subtle body" that transmigrates; hence the Buddhist doctrine, far from being revolutionary, actually repeats the *true* Hindu teaching.

Transmigration and Reincarnation.—Belief in transmigration, which is taken for granted in the major Asian religions and philosophies, was never dominant in the West. The doctrine was held in several Gnostic sects but subsequently disappeared or went underground. The Platonic and so-called Pythagorean doctrines, though cultivated in the Neoplatonic schools (Plotinus), exerted little influence on a Europe that was being conquered by Christianity. *Metensomatosis* (better known under the less felicitous term metempsychosis [*q.v.*]; other common terms are Gr. *metangismos* = Syr. *taspikha*, and Lat. *revolutio*) was a major Manichaean doctrine (*see* MANICHAEISM) derived, according to the 10th–11th century Arab scholar al-Biruni, from India. Its reappearance in the south of France in the 12th century (*see* CATHARI) is generally held to be due to influences of a Manichaean type. At about the same time and in the same area the doctrine also appeared in Jewish mystical circles and henceforth became a cardinal tenet of the Cabala (*q.v.*). It was revived in Christian Europe together with other Neoplatonic ideas during the Renaissance (*e.g.*, Giordano Bruno) and was subsequently taken up by Christian Cabalists and theosophists. In fact, most theosophical systems, whether ancient or modern, evince what appears to be a natural proclivity for linking their various spiritual metaphysics and cosmologies with the doctrine of reincarnation (*see* THEOSOPHY). Modern spiritualism, though it started in America, in its subsequent theoretical elaboration and theosophical development deliberately drew on Indian philosophy and on what was held to be the occult wisdom of the East. Contrary to Indian, Manichaean, and Cabalistic theories, however, most modern protagonists of the doctrine believe in human reincarnation only and reject the idea of transmigration into animal bodies. The doctrine was rejected as heretical by the Roman Catholic Church, which also condemned modern spiritualism (reply of the Holy Office of April 24, 1917). For a rejection of spiritualism from a fundamentalist Protestant point of view *see* L. E. Froom, *The Conditionalist Faith of Our Fathers* (1965).

In primitive religions a belief in what may be termed reincarnation appears in two main forms. One assumes that souls continue the round of existences in various natural species—often in insects, because these are found in or near the grave or the wooden soul-effigies. (This idea should not be confused with the notion that the soul itself appears as a small animal, particularly as a bird.) The other is connected with ideas about the relation of the living to the dead of the clan or tribe. Then it may be believed that pregnancy is due to an ancestral soul's entering the mother's body; in order to have a child, a woman would therefore pass, or worship at, a place inhabited by or associated with the souls of ancestors.

Immortality, the Afterlife, and Resurrection of the Dead. —*Dead and Living.*—It should be clear from the above that practically all religions entertain some notion of a soul. These notions

are based partly on prephilosophical, primitive ideas and partly on elaborations of philosophical concepts and their application to the requirements and experiences of religion. Among primitives some kind of survival is usually taken for granted, and the well-being of departed souls and their orderly progress to the land of the dead, as well as the prevention of their return as harmful spirits, are assured by funerary and seasonal rites. The dead visit the living, watch over their well-being, and, conversely, can avenge themselves if not paid sufficient attention (*see* ANCESTOR WORSHIP). They can also manifest themselves in various ways and even communicate with the living, *e.g.*, by means of spirit possession and in the institutionalized forms of shamanism (*q.v.*). Mediumistic contact with the dead as practised by spiritualism is in fact a modern version of shamanism but lacking its cultural sanction and institutionalized social function. The practice of communicating with the souls of the departed has given rise to a variety of new cults both in the West (Spiritualist churches) and in the East; the Cao Dai movement in Indochina is an interesting case of an Eastern cult heavily influenced by European spiritualism. Instances are also known of marriages of a living individual to a ghost partner.

In shamanistic and mediumistic contact with the spirit world, the distinction between departed souls and spirits of a different kind (gods, demons) is not always clearly made. The souls of departed saints, good spirits, and angels may become identified, and conversely the distinction among the souls of wicked men, evil spirits, and demons may become blurred. Spirit possession may be due to either, and rites of exorcism may be held to expel a demon as well as a former human soul (*e.g.*, a *dybbuk*). For the sake of terminological clarity, the following distinctions, drawn by R. Firth (*The Fate of the Soul*), may nevertheless be found helpful: whereas "soul" refers to the more or less immaterial survival-personality of a human individual, the term "spirit"—while including the soul—also denotes other categories of immaterial entities. The term "ghost" is generally used of the human survival-personality in its apparitional form after death.

Character of Life After Death.—Not all ancient religions took the permanent personal continuity of the individual soul for granted. In many primitive religions individuality is thought to persist for a few generations only; thereafter the departed soul joins the anonymous host of ancestors. But whereas modern man may have difficulty in entertaining the notion of an immortal soul, many primitive and archaic cultures had difficulty in conceiving the possibility of sudden and complete cessation of personal existence. Even when death was regarded as the final and inexorable end of human life, this end was not thought of as complete cessation but rather as a kind of existence in a bleak world of shadows —the Hades of the Greeks or the She'ol of the Hebrews (*see* HADES; HELL). Thus the psalmist admits that, as the shadowy doubles of their former full-blooded selves, "The dead do not praise the Lord, nor do any that go down into silence" (Ps. 115: 17), and when Saul wished to consult the dead Samuel the medium at Endor "brought up" the prophet's apparition from the underworld (I Sam. 28:8–14); she did not call down his soul from the upper spheres. Likewise did the weeping apparition of Patroclus come up to Achilles from the underworld (*Iliad* xxiii).

While the folklore and the ritual practices of the ancient world testify to a belief in some kind of afterlife, they hardly permit the generalization that an eternally blissful state was the normal expectation. Some civilizations seem to have held that only the virtuous (particularly warriors fallen in battle) would go to a kind of paradise, while others would suffer in a kind of hell. The view that the moral, spiritual, or ritual achievements of man in this life are insufficient to assure salvation and a blissful state for his soul is found almost everywhere. Hence almost all religions possess a variety of funerary rites and mortuary cults; *e.g.*, Roman Catholic practices intended to obtain remission of temporal punishment for poor souls in purgatory, Hindu *antyeshti* and *shrāddha* ceremonies, and the Parsee *baj* and *afringan*. The soul of the departed can benefit not only from rituals and prayers directly concerned with it but also from other works of merit (*e.g.*, acts of worship or charity, chanting of Holy Scriptures). The idea underlying these vicarious practices is the accumulation of disposable merit that can be transferred to the soul of the deceased. Indeed, many Mahayana Buddhist rituals are simply masses for the dead.

Immortality and Resurrection.—Significantly, when the ancient Jews began to feel that their historical, collective eschatology and their belief in a national restoration under a messiah were not enough—since they left the question of the destiny of the individual unanswered and failed to give a satisfactory account of the ways of divine justice in meting out reward and punishment—they evolved, or rather borrowed from Persia, the notion of a resurrection of the dead. Clearly the doctrine of the resurrection of the body implies a very different type of anthropology from that which produced the notion of an immortal spiritual soul substance.

The typical form of the doctrine of immortality as found in, for example, the Orphic and Platonic Greek tradition and in India is opposed to the idea of resurrection in two respects. In the first place, it tends to regard the independent spiritual substance which is the soul as the essential part of man. The body is merely its material clothing, and a vile and inferior one at that. The body is a prison (*ta sōma sēma*, as the Orphic proverb has it), and a considerable amount of philosophical and mythopoeic ingenuity had to be spent on accounting for the "descent" or "fall" of the pure, spiritual, and heavenly soul into this miserable body. Where, as in Christian teaching, the soul is not thought of as preexistent, the problem is, of course, different (*see* CREATIONISM AND TRADUCIANISM). It is obvious that on these premises the best hope that can be held out to the individual is the final separation, which is tantamount to liberation, of the soul from the body and its ascent to its celestial home. In fact, many systems of mystical contemplation and Yoga-like disciplines are designed to anticipate death and to realize the liberation from the body in this life. On this view it would be a most unfortunate fate for a soul to have to rejoin a body at the end of time. A similar evaluation of bodily life also underlies most theories concerning the transmigration of souls.

The doctrine of resurrection, on the other hand, in spite of its materialism and irrationality which have scandalized so many moderns, implicitly safeguards two fundamental biblical principles. The one is the integral or "holistic" conception of the human personality as an animated body: flesh vivified by the spirit. Resurrection of the body, if it means anything at all, can mean only that there is no way of talking of an eternal individual destiny unless one is prepared to define "individual" as this particular person with this particular body. The other point about resurrection is that it adheres to the pattern of an eschatological consummation of the process of history (*see* ESCHATOLOGY). The resurrection of Christ, in traditional Christian belief, is such an eschatological event inaugurating the new *aion*. In fact, some modern Christian theologians (*e.g.*, Karl Barth, Reinhold Niebuhr) insist that the symbol of the resurrection expresses the nature of the biblical message more adequately than does the "Greek" hope of immortality. It should be added that early Christian anthropology (St. Paul) was not based on the dualism body-soul but on that of flesh-spirit. Yet in due course the latter dualism became identified with the former.

The tension between the two conflicting anthropologies is well illustrated by the compromise solution according to which resurrection means the return of the soul to a spiritual ("glorified") body. Of course these contradictions appear as such only in a rational analysis bent on distinguishing "ideal types." In actual practice and in the eyes of the ordinary believer the divergencies are as good as nonexistent: individual souls are provisionally judged after death and go to heaven or, alternatively, to hell; from this discarnate state they will be called to the final judgment and resurrection. This view is characteristic not only of traditional Judaism and Christianity (Jesus adopted the Pharisaic dogma of the resurrection, which was denied, as unscriptural, by the Sadducees) but also of Zoroastrianism. According to the latter, man's soul (*fravashi*) is judged provisionally after death, pending a final purgation and resurrection (*see* ZOROASTRIANISM). The Jewish Cabalists even combined belief in a hereafter, the

transmigration of souls, and the resurrection of the body.

Release From, and Acquiring, Immortality.—According to the more fully developed Indian systems of thought, immortality was, as it were, natural (*samsara*), but as long as it meant being bound to the wheel of *karma* (*q.v.*), it was negative. The aim was not immortality but liberation. For the ancient Egyptians, on the other hand, immortality had to be laboriously acquired, by means of a ritual assimilation of the departed to the resurrected Osiris (*q.v.*). This rebirth to immortality was at first the privilege of the king (himself divine) but subsequently became accessible to nobles and even to commoners. In fact, "immortal" was synonymous with "divine," since, in Greek as well as Egyptian religion, it was precisely their mortality that distinguished men from the gods, who otherwise could be very similar to human beings and even of common origin with them. Hence the gift of immortality, as bestowed, for example, by initiation into the mystery cults (*see* MYSTERY), was tantamount to deification. Immortality was the boon of salvation held out by the mystery religions, and some of the related notions and practices of antiquity may have affinities with the Christian formulation of salvation as rebirth to immortality by sharing in the resurrection-life of Christ.

Perfect and Imperfect.—Whatever the philosophical difficulties of justifying the notion of an immortal but not eternal (since created) soul, once the idea is accepted it almost automatically becomes the focal point of man's speculations about his spiritual, moral, and intellectual nature and destiny. Since the body, matter, and this world in general are but the temporary housing of the spiritual soul, and moreover a source of temptation and of entanglement with lower things, this preoccupation was often accompanied by contempt of, or indifference to, things bodily, material, and temporal. Religion being generally considered to be concerned with things eternal and nontemporal, its main business was the cure and the salvation of souls. This cure of souls could assume philosophical, ethical, or ritualistic (*e.g.*, sacramental) emphasis. Thus the Aristotelian tradition, which associated the immortal part of the soul with the intellect, clearly conceived of moral perfection *sub specie intellectus* (Averroës, Maimonides). For many Muslim philosophers and mystics *nafs* (soul, *psyche*) denoted man as a living organism, the bearer of appetites and drives directed toward the body, whereas *'aql* (intellect, *nous*) was the truly spiritual principle, alien to this world and striving to return to its heavenly home. Where, on the other hand, man's spiritual calling was defined in terms of piety, love of God, faith, obedience, or good works, it could happen that intellect and reason were decried as of the devil. Man's moral conscience too—God's voice in the heart of man or, in the words of St. Bonaventura, *praeco Dei et nuntius*—could, accordingly, be regarded as a function of reason (possibly of a "practical reason," as in Kant) or, on the contrary, of a special moral faculty of the soul.

In many religions the division between the pure and perfect and the impure and imperfect is not identical with that between soul (or intellect) and body. There are evil ("fallen") souls; and bad *karma*, due to earlier evil deeds, may result in a degeneration of the soul. Adam's fall, according to Christian teaching, constitutes the Original Sin as a result of which human nature, and the soul in particular, is corrupted; though Roman Catholic and Protestant dogmatics differ as to the degree of this corruption.

Summary.—The idea of a soul can be viewed from different angles. As a scientific concept it seems useless (except, perhaps, as a hypothetical construct for theorizing about the facts alleged by psychical research). In primitive and some higher religions, souls, like ghosts, are simply and naïvely taken for granted, though reasons of a philosophical and psychological kind may be adduced subsequently. From the point of view of the theologian and the moralist (*e.g.*, Kant, Butler, Royce) the assumption that souls exist and that they are immortal renders a moral view of God and of human life and suffering possible. The belief owes its strength to the fact that the notion of a soul functions as one of the symbols—concretizing and reifying, no doubt, like all symbols—of man's self-consciousness and of his awareness of the mystery of his individuality and of the spiritual dimensions (including inwardness, mentation, morality) of his existence.

Ideas about the nature or origin of the soul serve to determine man's image of himself, as an individual being or as a member of a clan, tribe, religious community, etc., and to explain his character or fate. Relations with the souls of ancestors, or the departed in general, confirm social solidarity and group consciousness and may impart a sense of continuity to society. Doctrines regarding the future of the soul function as moral sanctions not only in an individual but also in a social sense: they serve to separate the sheep from the goats in some more ultimate realm, whereas in our present world the social lines of division do not coincide with those envisaged by the moral system. Doctrines regarding the hereafter may therefore be said to assert as absolute and definite those values which society affirms although individual and historical experience of actual life may have failed to validate them.

"Now that Sartre has replaced Dante as our eschatological authority" (R. Firth, *The Fate of The Soul*, p. 14; Cambridge University Press, 1955), statements about the soul and its fate in the hereafter tend to be interpreted as statements about the human condition and as expressions of attitudes about behaviour in this world. Contemporary opinions regarding the soul range from outright denial on logical-analytical or naturalistic-positivistic grounds, through the modern, existentially demythologized interpretation of the ancient images and concepts, to acceptance of the traditional doctrines of the great religions.

SOULOUQUE, FAUSTIN ÉLIE (1789?–1867), Negro emperor of Haiti, was born a slave about 1789 while Haiti was under French rule. He participated in the successful Haitian revolt against the French in 1803 and thereafter continued as an officer in the Haitian army. He was made president of Haiti in 1847 because the mulatto leaders who had dominated the government under several figurehead Negro presidents thought that his illiteracy and ignorance would make him easy to control. He soon turned against his would-be advisers and ruled as a cruel and corrupt despot, proclaiming himself Emperor Faustin I in 1849 and creating a numerous nobility. Many of the mulatto leaders were killed or exiled. Soulouque made several costly and unsuccessful attempts to conquer the Dominican Republic, until the U.S. and France and Great Britain in 1851 demanded that he desist. He later renewed his attacks and in 1855 was defeated by the Dominican army. In 1859 he was ousted after the chief of his general staff, realizing that the emperor suspected his loyalty, led a revolt. Soulouque escaped and went into exile. He died in 1867.

SOULT, NICOLAS JEAN DE DIEU, DUC DE DALMATIE (1769–1851), French soldier, one of Napoleon's group of able commanders, was born on March 29, 1769, at St. Amans-la-Bastide (now St. Amans-Soult, Tarn). On the death of his father, a notary, he enlisted (April 1785) in the French infantry, and on the outbreak of the Revolution he was a sergeant at Strasbourg. He served under Adam Philippe de Custine (1792) and under Lazare Hoche (1793) on the Moselle, and from 1794 under François Joseph Lefebvre, being made a general for his conduct at the Battle of Fleurus (June 1794). In March 1799 he replaced the wounded Lefebvre in a division at the Battle of Stockach. The army regarded him so highly that André Masséna, who did not know him, called him to Switzerland as his chief lieutenant. He distinguished himself in the Battle of Zürich (September 1799), and with Masséna in the hills above Genoa in 1800 he increased his reputation for vigour, boldness, and method. He was put in charge of the southern part of the Kingdom of Naples (1800–02)

and in 1804 was made a marshal of France. He commanded a corps at Ulm (October 1805), and after his decisive attack at Austerlitz (December) he was considered "the best tactician of Europe." He was equally successful at Jena (October 1806), but in Poland his attacks at Eylau and Heilsberg (February and June 1807) were costly and indecisive. Created duc de Dalmatie after the Treaties of Tilsit, he went to Spain late in 1808 and pursued Sir John Moore to Corunna (January 1809).

For the next four years Soult remained in Spain, and his military history is that of the Peninsular War (*q.v.*). Surprised (May 1809) and driven from Oporto by Sir Arthur Wellesley (later duke of Wellington), he retreated into Spain, where his arrival in the Tagus Valley caused Wellesley to withdraw from Talavera. Napoleon ignored the Oporto failure and sent him to Madrid to direct, under Joseph Bonaparte, all the French armies in Spain. The results were brilliant; his concentration crushed the Spanish counteroffensive at Ocaña (November 1809). As governor of Andalusia he supported Masséna's attack on the English in Portugal, and took Badajoz in March 1811. He was, however, defeated in May by William Carr (later Viscount) Beresford at Albuera, southeast of Badajoz. The defeat of Auguste Marmont at Salamanca (July 1812) forced him to evacuate Andalusia, and although he subsequently recovered Madrid, he failed to give battle to Wellington at Salamanca in November. Recalled to France (early 1813), he then served in Germany, but on the news of Joseph Bonaparte's defeat at Vitoria (June 1813), Napoleon sent him back to Spain with full powers. His immediate offensive across the Pyrenees was too bold for his wearied and outnumbered troops; he subsequently held and then was forced from each river line in southwestern France, sustaining his last defeat at Toulouse (April 1814), four days after Napoleon had abdicated.

Marshal Soult's political career was less creditable, and it has been said of him that he showed character only in the face of the enemy. At the First Restoration he declared himself a royalist and was appointed minister of war, but during the Hundred Days he again supported Napoleon, acting as his chief of staff at Waterloo. Exiled at the Second Restoration, he was recalled in 1819. Under Louis Philippe he presided over three ministries (October 1832–July 1834, May 1839–March 1840, October 1840–September 1847), usually holding, as well as the office of president of the council, that of minister of war, which he had previously held under Jacques Laffitte and Casimir Périer (November 1830–May 1832). He was responsible for the conquest of Algeria carried out by Thomas Robert Bugeaud de la Piconnerie. In 1847 he was made marshal general of France, a dignity previously held only by Turenne, Villars, and Maurice de Saxe. In 1848, when Louis Philippe was overthrown, he declared himself a republican. He died at St. Amans-Soult on Nov. 26, 1851. His *Memoires* (three volumes) appeared in 1854. (I. D. E.; X.)

SOUND. This article is divided into the following sections and subsections:

I. WHAT IS SOUND?

When a person speaks he is said to emit sound stimuli. Anyone in the vicinity with normal hearing (or in default thereof a suitable hearing aid) is said to experience sound. This common experience reflects a phenomenon of the greatest significance to human beings, who may be considered to be immersed in a world of sound stimuli that have notable influence on most everyday activities. The importance of this experience called sound is reflected in the large number of words descriptive of the different kinds of sound that fill human awareness. Inanimate nature produces the thunder of the storm, the roar and pounding of the surf, the whistling of the wind, the whispering of the trees, the patter of rain, the rippling and gurgling of running water, the humming of wires, the creaking of snow. Even more rich is the vocabulary descriptive of the sounds of living things: the barking and snarling of dogs, mewing of cats, crowing of fowl, roaring of lions, hissing of snakes, the lowing and bellowing of cattle, blatting of goats, chirping of birds and insects, screaming of gulls, crying of infants, and so on.

Not content with all the racket around him over which he has little or no control, man has contrived to produce sounds of almost infinite variety giving both pleasure and pain to countless millions. The boom of cannon, the crack of the pistol, the rattle of musketry and machine-gun fire, the whine of the shell, and the blast of its explosion are unpleasantly familiar. The whir of machinery and the ticking of clocks have more agreeable connotations though they might be distracting to some people. But the melody and harmony of music are generally admitted to contribute aesthetic enjoyment.

What are these stimuli that produce so large a part of man's waking experience? This article gives the answers of physics to that question; it shows that there is far more to the experience called sound than "meets the ear" and that stimuli beyond the range of hearing are in some respects the most important for modern physics and its technical applications. Sound stimuli are physical and the branch of physics that describes them is called acoustics (from the Greek word *akoustikos*, relating to hearing). Physics as an abstract science employs mathematical analysis freely. Because general readers understandably prefer everyday language, this article introduces the subject with a general nonmathematical survey; for readers who seek a deeper understanding, a more analytical account follows.

1. Motion and Sound.—It is obvious to even the most casual observer that a thorough analysis of all that is involved in the emission of any one of the stimuli mentioned above must be complex. To make clear in detail what goes on, for example, in the head and larynx when one speaks would require explanations drawn from physiology, psychology, and physics, with, of course, the aid of mathematics. Nevertheless, it is generally agreed that the r sult is some motion of the air in front of the mouth. It is generally accepted that when a person hears (except in drea

hallucinations) there is some motion of the air at the entrance to his ear.

A careful examination of sound-producing phenomena consistently shows evidence of motion in some medium. This is satisfying to physicists, who have long sought to account for most phenomena in terms of motion, which they believe they understand. To those whose ideas of motion are confined to such solid things as automobiles and airplanes, the association of motion with sound may provide some difficulty. Realizing that in open, still air it is possible to hear a cricket chirp at a distance of half a mile, the skeptic asks how such a small insect can move the mass of air (more than 1,000,000 tons) in a hemisphere with a radius of half a mile so that the air near his ear may move sufficiently to lead to hearing. The question rests on the assumption that the sound producer must move all the surrounding air all at once to produce the experience of sound. However, air is a compressible elastic fluid (*i.e.*, it can be squeezed) so that motion can occur in one part without appearing simultaneously everywhere else. One of the interesting properties of such a medium is that if one small region is squeezed, it does not stay that way. Once squeezed it tends to expand again and compresses (*i.e.*, moves) an adjoining portion of the medium, which in turn repeats the process. The result is that portions of the medium far from the source get squeezed at a time later than the original disturbance. This kind of motion, communicated in time from one part of a medium to another, is called wave motion. Thus the sound stimulus travels in air as a compressional (or squeeze) wave.

2. Velocity and Intensity.—The standard visual illustration of wave motion is provided by the ripples produced on the surface of water by a stone. Strikingly, the water itself does not move outward from the centre of the disturbance, only the distortion of the surface (the ripple) does. The distance traveled by the ripple per unit time is called the wave velocity. All waves have a finite velocity that varies greatly from type to type. Thus ripples on the surface of water may move only a metre or so per second. Light in free space, on the other hand, travels at the enormous rate of 3×10^8 m. per sec. The velocity of sound waves in air increases with temperature, but at room temperature it is about 344 m. (1,125 ft.) per sec. (roughly, 767 miles per hour). Since its value is relatively small compared with that of light, the sound of a distant cannon is heard some time after the puff of smoke is seen.

In fresh water sound waves have a velocity of about 1,500 m. per second at room temperature.

The everyday distinction between loud and soft sounds rests on differences in the magnitude of motions involved in wave propagation. In normal conversation the pressure of the air in front of the mouth of the speaker is changed at most by only about one-millionth of the standard atmospheric pressure. At the same time the accompanying motion that produces the compression leads to an air-flow velocity with a maximum value of only two one-hundredths of a centimetre per second. That such small changes in the air lead to hearing should strengthen respect for the sensitivity of the ear structures. Since motion implies energy, sound waves represent the transmission of mechanical energy. An average rate of transfer of only 10^{-16} (1 divided by 10 raised to the 16th power) watt per square centimetre of acoustic power is enough to produce hearing in a normal young person. This means that mechanical energy of only about 10^{-10} erg (or 3×10^{-24} kw-hr.) can produce an identifiable signal in the normal ear; in this respect the ear is as sensitive as the eye. The average power transmission in a sound wave per unit area is called its intensity. The modern unit for this quantity is the decibel (abbreviated db.), which indicates intensity relative to a standard that usually corresponds to minimum audibility (average excess pressure 2×10^{-4} dynes/cm^2). On this basis conversational speech has an intensity of about 60 db. at a distance of a few feet, traffic at a busy intersection 75 db.; a boiler factory can reach a level of 130 db.

As a source of sound in the open moves farther off (for example, an airplane) the less distinctly it is heard. The intensity of sound in an unenclosed space thus decreases with distance from the source. This is basically a matter of geometry. The airplane may be thought of as emitting the same amount of energy every second in every direction, but as the distance increases this energy spreads over a larger and larger area, and hence the average flow per unit area is diminished. Thus, if the sound disturbance travels with the same velocity in every direction, it will at any given instant reach the surface of a sphere with the source at the centre and with radius equal to the product of the velocity and the elapsed time. Hence the intensity should be expected to decrease in the same ratio as the surface of the sphere increases with its radius; *i.e.*, with the square of the distance from the source. However, it is observed that the drop is greater than predicted by this inverse-square relationship. Apparently some of the energy represented by the sound disturbance is absorbed and changed into heat. This absorption is particularly noticeable in a viscous liquid like glycerol. In air it is accentuated by reflection, refraction, and scattering. The situation is unfortunately more complicated for a source of sound on the ground or under water (near the surface), and even more involved when the source is enclosed in a room.

3. Reflection and Refraction.—Sound waves manifest other properties besides velocity and intensity. Like light waves, they are reflected from surfaces separating media of different properties, and refracted (*i.e.*, bent from the original direction of propagation) in crossing such surfaces obliquely. A familiar example of reflection is the echo produced near a high wall or cliff. This is most readily interpreted as the reflection of the original sound wave from the solid surface, verified by the observation that the time elapsing is that required for the wave to reach the cliff and for the reflected disturbance to return.

Important also is the concept of acoustic image. Like its optical counterpart this is an imaginary source of sound which, if it were located exactly as far behind the reflecting surface as the initial source is in front of it and if the surface were then removed, would give the observed echo at the proper time and with the proper intensity.

It is much easier to speak audibly in a closed room than in the open air. This is another illustration of reflection; the sound waves from the speaker reach the listener not merely in the direct line between the two but also by many paths involving reflection by the walls, floor, and ceiling. Consequently much energy that would be dissipated in all directions out of doors is, so to speak, trapped in the room and helps build up the sound intensity at every point. In a not-too-large room the echoes from the reflecting surfaces merge to produce a continuous sound or reverberation that can impair distinctness of hearing if it lasts too long. Such a room needs acoustic treatment to cut down reflection; *e.g.*, by the introduction of suitable absorbing materials.

Refraction of sound waves is less obvious than in the case of light but produces well-recognized effects. Sound waves travel faster in warm air than cold and since the atmosphere almost always shows vertical temperature differences the waves rarely pass through it in straight lines from the source. Normally there is a negative temperature gradient (*i.e.*, the air becomes increasingly cooler with altitude) and the sound rays (see *Wave Fronts and Rays* below) are bent upward; hence the range of hearing in the horizontal direction is materially reduced. When the temperature gradient is positive (so-called temperature inversion since the air warms with altitude; infrequent in most localities, but seen occasionally in early daylight hours after a clear, wind-free night) upward-moving rays tend to be bent downward, giving a longer range of transmission. Refraction of light through air of varying temperature can produce a mirage (*q.v.*); acoustic mirages also occur under similar conditions, and sound may appear to come from a different direction than it would through a homogeneous medium. These effects are complicated by refraction arising from the motion of the medium (*e.g.*, winds). Also, sound waves travel better with the wind than against it since propagation velocity is changed by addition with wind velocity.

Refraction of sound waves plays a significant and embarrassing role in gun ranging, an acoustical method of locating guns by the sounds of their firing. The reflection and refraction of sound waves in water have practical importance in detecting underwater objects (*e.g.*, a submarine) acoustically. Detection of reflected

sound waves leads to an estimate of range and bearing of the object being sought; but refraction or bending produced by temperature gradients in the water introduces complications (*see* ECHO SOUNDER).

4. Diffraction and Scattering.—One of the most striking properties of sound waves is their tendency to bend around obstacles, permitting a source to be heard around a corner. This is an illustration of the general wave characteristic called diffraction. Light waves do not diffract to such a degree and a light source cannot be seen around a corner through this mechanism.

Because of diffraction objects of ordinary size cannot form sharp acoustic shadows (*see* SHADOW).

An interesting example of diffraction is provided by the human head. Since the ear structures are imbedded in a roughly spherical, more or less solid sphere, the ticking of a watch sounds different in front of the head than it does at the same distance directly behind. Theory and experiment indicate that because of diffraction a source of sound produces a greater intensity at the head if it lies on an extension of the line joining the ears than if it is at the same distance directly in front of the head. This effect has significant bearing on the testing of microphones.

When the diffracting obstacle is relatively small (*e.g.*, a fog droplet), the sound wave is said to be scattered, since the bending makes it turn in all directions from the original.

5. Pitch, Frequency, and Wavelength.—An ordinary air siren produces sound waves by interrupting jets of air at different rates by means of a rotating disk with orifices in its periphery. The more rapidly the interruption takes place (*i.e.*, the greater the number of separate puffs of air per unit time) the higher the perceived pitch. A source of sound in which the disturbance repeats regularly like the puffs of air in the siren is said to produce a harmonic sound wave characterized by a definite frequency. This is defined as the number of times per second the disturbance in the wave at any point is repeated.

The relation between pitch and frequency in a sound wave like that associated with the human voice or ordinary musical instruments is more complex than for a pure harmonic wave as emitted by a carefully made tuning fork. The fork is said to produce a pure tone of definite single frequency. In a harmonic sound wave in air the compression varies periodically at every point. The time for one complete cycle of pressure change at any point is called the period of the wave. The period in seconds is equal to the reciprocal of the frequency (represented by the number of complete cycles per second).

Sounds of all frequencies are not heard equally well. If a hand is waved back and forth periodically with a frequency less than 15 cycles per second, no sound is heard. An object vibrating faster than this will tend to be audible if the intensity is sufficiently great. When frequency is increased beyond 20,000 cycles per second, audibility ceases for most people, and with advancing age this frequency threshold diminishes decidedly. Such waves of very high frequency are inaudible no matter how great their intensity. These are called ultrasonic waves and play an important role in modern acoustics. Ultrasonic waves tend to travel in beams like light, while low-frequency sound waves tend to spread in every direction from the source. Obviously such high-frequency waves need special devices for their production and detection. Much of the progress of acoustics after about 1925 came from the development of such equipment, which produced frequencies up to 100,000,000 cycles per second.

Harmonic waves are also characterized by wavelength: the distance between successive points in a spreading wave at which the disturbance is exactly the same and doing the same thing (*i.e.*, getting larger or smaller). At two such points the phase of the wave is said to be effectively the same. Since the disturbance in a wave travels a distance of one wavelength in one period, the product of wavelength and frequency equals the wave velocity. This important relation holds for all periodic waves. It means that high-frequency acoustic waves in a given medium have smaller wavelength than do low-frequency sounds. Thus in water a wave of frequency 1,000 cycles (1 kilocycle: kc.) has a wavelength of approximately 1.5 m., whereas for a frequency of 1,000,000 cycles (1 megacycle: Mc.) the corresponding wavelength is only 1.5 mm.

Many of the properties of sound waves depend on frequency. Very few sounds in daily experience are pure tones characterized by a single frequency; most can be considered as arising from more or less complicated combinations of harmonic waves, each of definite frequency. One or more frequencies will often predominate and help give the sound its observed quality. In general a high-frequency wave is bent by diffraction less than is a low-frequency wave, and permits an obstacle to cast a sharper acoustic shadow. (A corresponding phenomenon occurs with visible light, where the frequency is very much higher than that of any sound wave.) When sound waves are scattered by objects whose dimensions are small compared with the wavelength, the high-frequency components are scattered much more effectively than those of low frequency. This is analogous to the scattering of sunlight by dust and molecular particles of the atmosphere; the short wavelength or high-frequency light (*i.e.*, the blue) is scattered much more than the long wavelength (red) to give the sky its characteristic colours.

6. Wave Fronts and Rays.—Recall that an audible wave tends to spread out in all directions from the source. However, a beam of sound can be produced if the frequency is high enough. It is helpful in describing this situation to use the concept of wave front: a surface of such kind that at any instant the disturbance characterizing the sound wave is the same at every point.

An example is an airplane propeller radiating a sound wave into the surrounding air. At any instant the state of compression of the air in this wave will be the same on the surface of a sphere with centre at the propeller. This sphere may be called a wave front with a radius that increases from the propeller at a rate equal to the velocity of the sound wave. The expanding circular ripples on water produced by a dropped stone represent a clear analogy. A spherical front will not develop if a sound wave is confined to a tube of constant cross section; *e.g.*, a speaking tube. Though the propagation of the disturbance is complicated by reflections from the walls of the tube, it is approximately accurate to assume that a plane (flat) wave front perpendicular to the direction of propagation will traverse the tube.

Plane and spherical fronts are the most important types encountered in sound-wave propagation. As distance from the source increases the effective part of a spherical wave becomes increasingly flat and plane-wavelike.

Lines perpendicular to a wave front are known as rays. These indicate at any instant the direction in which the wave front is moving at any place. For many purposes it is convenient to describe sound-wave transmission in terms of rays, as in the analogous case of light. However, the wavelength is long compared with that of visible light; consequently ray acoustics is in general by no means as accurate a representation as ray optics. It is more difficult to produce a beam of sound waves than a beam of light, but it can be done if the wavelength is sufficiently small compared with the size of the sound source. The mechanism by which this takes place is called interference and is explained below. Such sound beams are very useful in underwater detection.

II. ANALYSIS OF ACOUSTIC PROPAGATION

1. Wave Functions.—The mathematical treatment of sound waves in general is very complicated. It is simplest to begin with the kind of wave that can be produced in a long, flexible string by flicking one end. Since the kink travels along the string (fig. 1) at right angles to the direction of propagation it is called a transverse wave. This differs from a sound wave in which the compression moves in the same direction as the wave; thus sound waves are called longitudinal. Each particle of the fluid in this case is displaced from its equilibrium position in the direction of the wave propagation. However, the mathematical analysis in its more fundamental aspects is the same for both kinds of wave.

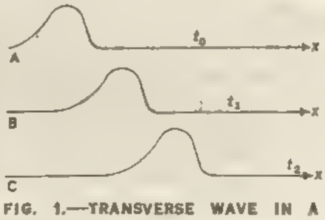

FIG. 1.—TRANSVERSE WAVE IN A STRING

If a snapshot were made of the kinked string at a given instant t_0, it might look like A in fig. 1. Here the disturbance, measured by the distance each part of the string has been displaced from its undisturbed position, can be represented by a mathematical function $f(x)$, where x denotes distance along the string. At a later time t_1 the disturbance has moved a distance $V(t_1 - t_0)$, where V is the velocity of the wave, so the same function $f(x)$ reappears, but displaced (B in fig. 1); likewise for t_2 as indicated in C. The mathematical function of x that describes motion along the positive x axis with velocity V is

$$\xi = f(x - Vt) \qquad (1)$$

The Greek letter ξ (*i.e.*, xi) denotes the displacement (*i.e.*, the measure) of the disturbance. If the wave travels in the negative x direction the corresponding wave function is

$$\xi = g(x + Vt) \qquad (2)$$

Note that there is nothing periodic about equations (1) and (2). However, most sound waves of interest have frequency and wavelength; *i.e.*, they are periodic. The simplest of all periodic waves is the harmonic, in which equation (1) takes the form

$$\xi = A \sin(\omega t - kx) = -A \sin k(x - \omega/k \cdot t) \qquad (3)$$

This is evidently in the proper form for a wave function if ω/k is interpreted as equal to the velocity V. But what are ω and k? The displacement of a particular point x_0 of the string traversed by such a wave varies with time; it is sinusoidal with period $P = 2\pi/\omega$ or frequency $\nu = \omega/2\pi$, which fixes the frequency of the wave. A picture of the string at the instant t_0 will show that the displacement varies sinusoidally with x and the distance between successive points of maximum displacement in the same direction is $2\pi/k$. This has been defined as the wavelength λ of the wave. Hence

$$\nu = \omega/2\pi, \lambda = 2\pi/k \qquad (4)$$

Since $\omega/k = V$, this leads to the important relation

$$\nu\lambda = V \qquad (5)$$

This relation holds for any harmonic wave. It is worth noting that if the cosine function were used in place of the sine function in equation (3) the physical meaning would not be altered. The quantity ω is often referred to as the angular frequency of the wave.

2. Equation of Wave Motion.—If ξ in equation (3) is differentiated twice with respect to x (keeping t constant), and then twice with respect to t (keeping x constant), it can be shown, keeping in mind equation (5), that

$$\frac{\partial^2\xi}{\partial t^2} = V^2\frac{\partial^2\xi}{\partial x^2} \qquad (6)$$

The existence of this equation also follows from the general wave functions: equations (1) and (2). It is called the general differential equation for wave motion in the x direction. Its general solution is the sum of equations (1) and (2) representing general waves progressing in both positive and negative x directions. The physical advantage of a partial differential statement like equation (6) is that it contains the description of so much in so compact a form. The task of theoretical physics in almost every branch may be said to be the development of such general equations. The whole theory of the propagation of normal-intensity sound waves is implied in equation (6) and its generalization to three dimensions (in which any point in space has the coordinates x, y, z):

$$\frac{\partial^2\xi}{\partial t^2} = V^2\left(\frac{\partial^2\xi}{\partial x^2} + \frac{\partial^2\xi}{\partial y^2} + \frac{\partial^2\xi}{\partial z^2}\right) \qquad (7)$$

Physicists feel that they understand something about the propagation of sound waves since equations (6) and (7) are a logical consequence of the behaviour of a fluid when it is compressed.

The behaviour of an ideal fluid when disturbed from its state of rest is described (*see* MECHANICS, FLUID) by three fundamental equations. The equation of continuity indicates that no matter how the fluid moves, as long as it hangs together, there must be conservation of mass. The equation of motion states that the total time rate of change of velocity of a particle of fluid must equal the force per unit mass acting on the particle. For purely compressional disturbances the rate is proportional to the negative of the rate of change of the excess pressure with distance. Finally the equation of state connects the change in pressure with the change in density. This shows that the excess pressure p_e produced by any disturbance in the fluid (*i.e.*, the difference between the actual pressure and the equilibrium pressure prevailing before the disturbance) is directly proportional to the excess density ρ_e (*i.e.*, the difference between the actual density in the disturbed fluid and the equilibrium density). The coefficient of proportionality is usually written as c^2. This idealized static equation of state takes no account of the time required for the imposition of excess pressure to produce the excess density.

Mathematical combination of the three equations leads to a statement of the same form as equation (6). When a fluid is disturbed mechanically the pressure is bound to change; and this leads to motion of the fluid as well as compression or rarefaction (change in density). This must take place in such a way that no mass is lost (continuity), and if the fluid is elastic the compression will move through the fluid as a wave. The result of the combination can be expressed conveniently in terms of excess pressure p_e as

$$\partial^2 p_e/\partial t^2 = c^2\partial^2 p_e/\partial x^2 \qquad (8)$$

having the same mathematical form as equation (6), but with p_e in place of ξ and c in place of V. Physically it means that the acoustical disturbance represented by the excess pressure is propagated as a wave along the x axis with velocity c. It can be shown that the displacement ξ and the excess density ρ_e are propagated in the same way.

In the mathematical deduction leading to equation (8) it has been assumed that the disturbance is not too extreme. Specifically this means that the ratio of the excess density to the equilibrium density (usually called the condensation) is very small compared with unity.

This also means that the gradient of the particle displacement in the fluid (*i.e.*, $\partial\xi/\partial x$) is much smaller than unity. Moreover the flow or particle velocity associated with the disturbance must be very small compared with c (the wave velocity). These conditions prevail for all normal acoustic phenomena associated with speech, sound reproduction, and even for most acoustic transmission, as in underwater sound signaling. However, they fail to hold for sounds produced by explosions, by the rush of gas in a jet airplane, or for sound waves that can produce cavitation (*i.e.*, the appearance of bubbles) in liquids. High-intensity sound (macrosonics) is describable not by equations (6) or (8), but by

$$\partial^2\xi/\partial t^2 = \frac{V^2\partial^2\xi/\partial x^2}{(1 + \partial\xi/\partial x)^{\gamma+1}} \qquad (9)$$

in which the quantity γ in the exponent, if the medium is a gas, is the ratio C_p/C_v, where C_v is the specific heat of the gas at constant volume and C_p is the specific heat of the gas at constant pressure (*see* CALORIMETRY). The equation can also hold for solid and liquid media but γ will then have a different meaning; in the simplest cases it is unity, but it can have higher values. The solution of equation (9) is not so simple as that of equation (6) (to which it reduces for $\partial\xi/\partial x << 1$). For $\gamma = 1$, for example, the solution can be put in the form

$$\partial\xi/\partial t = f[x + \xi - (V + \partial\xi/\partial t)\, t] \qquad (10)$$

where f is an arbitrary function. The physical meaning of this complicated expression is that the various parts of the wave profile (*see* fig. 1) do not move forward with the same velocity. Rather, the top of the hump moves faster than the bottom and hence a disturbance that starts out with a symmetrical profile as in fig. 2A will become asymmetric as in fig. 2B in which the front of the profile will be steeper than the rear. Eventually the front will become vertical and then lean over so that

A B
FIG. 2

its top is farther to the right than its bottom until the wave breaks, as in waves at the seashore. The only way a macrosonic wave can maintain its profile or wave form is through some kind of damping mechanism (*e.g.*, viscosity).

3. Velocity in Fluids.—Recall that the velocity of sound waves in an ideal fluid is given by c in the expression

$$c = \sqrt{p_e/\rho_e} \tag{11}$$

The evaluation of the radical for a liquid follows from the definition of the bulk modulus

$$B = \frac{p_e}{\rho_e/\rho} \tag{12}$$

whence

$$c = \sqrt{B/\rho} = \sqrt{1/\rho K} \tag{13}$$

where K is the compressibility. Since liquids have a relatively small compressibility that changes but little with the density, it is in general adequate to insert ρ_0 (the mean density) for ρ in equation (13).

For gases the situation is different; thus for an ideal gas the equation of state takes the form

$$p/\rho = RT \tag{14}$$

where R is the so-called gas constant per unit mass and T is the absolute temperature. This gives

$$p_e/\rho_e = RT = p/\rho \tag{15}$$

if the temperature remains constant. Hence if the compressional disturbance in the gas takes place isothermally, the velocity has the form

$$c = \sqrt{p/\rho} \tag{16}$$

This formula was first derived by Sir Isaac Newton. It gives, however, a value definitely smaller than that measured for the nearly ideal gases like oxygen and nitrogen. On the other hand, if it is assumed that the acoustic disturbance takes place adiabatically, equation (14) must be supplemented by

$$p/\rho^\gamma = p_0/\rho_0{}^\gamma \tag{17}$$

in which $\gamma = C_p/C_v$ is the ratio of the specific heat of the gas at constant pressure to that at constant volume. It follows then that

$$c = \sqrt{\gamma p/\rho} \tag{18}$$

This result agrees so well with experiment that the measurement of sound-wave velocity became a standard way of evaluating γ, and it is generally assumed that acoustic disturbances in an ideal fluid take place adiabatically. It must not be assumed offhand that the same holds for a viscous fluid, for example, or one that conducts heat. For liquids (equation [13]) the adiabatic compressibility must be used in computing c, but the difference between adiabatic and isothermal compressibilities here is generally small (*see* THERMODYNAMICS).

For an ideal gas it follows from equations (14) and (17) that the velocity of sound waves is independent of the pressure. On the other hand c does depend on the temperature:

$$c = \sqrt{\gamma RT} \tag{19}$$

If the velocity at 0° C is c_0, that at t° C is clearly

$$c_t = c_0\sqrt{1 + t/273} \tag{20}$$

For dry air under standard conditions $c_0 = 331.3$ m. per sec. This agrees well with measurements made in the open air, considering that they are extremely difficult to perform precisely; atmospheric conditions are rarely uniform, and sound-wave transmission in the open air is complicated by nonhomogeneity and wind.

For empirical work with gases equation (19) must be modified, since the equation of state is no longer as given in equation (14). It is now more convenient to revert to equation (13). Since the adiabatic bulk modulus must be used for B, it is seen that $B_{ad} = \gamma B_{iso}$ and by definition

$$B_{iso} = \rho(\partial p/\partial \rho)_T \tag{21}$$

The expression for the velocity c then becomes

$$c = \sqrt{\gamma(\partial p/\partial \rho)_T} \tag{22}$$

For the ideal gas as described in equation (14) this formula yields equation (18). One useful form of the equation of state of an empirical gas is

$$p/\rho = RT(1 + \beta\rho + C\rho^2 + \ldots) \tag{23}$$

The quantities β and C are known as the second and third virial coefficients per gram of gas respectively and are functions of the temperature. Substituting in equation (22) yields

$$c = \sqrt{\gamma RT(1 + 2\beta\rho + 3C\rho^2 + \ldots)} \tag{24}$$

In this form it is clear that the velocity of sound waves depends on the pressure as well as the temperature. The effect in air is small except at very low temperatures. Thus for air at 90.1° K the velocity at 1 atm. pressure is about 188 m. per sec. (A. van Itterbeek and W. van Doninck), whereas at 0.2 atm. it is 191 m. per sec. (Note that at this temperature β is negative.)

The experimental determination of the velocity of sound waves can be used as a method of measuring the virial coefficient β as well as γ. It is also possible to calculate theoretically the velocity of sound waves in a mixture of two gases and then use the formula to determine the relative concentrations of the components by a velocity measurement (H. B. Dixon and G. Greenwood).

As might be expected, the velocity is most sharply dependent on pressure in the neighbourhood of the critical point. Thus in carbon dioxide at 31° C, for example, the value of c drops from about 260 m. per sec. at 20 atm. pressure to a minimum of 150 m. per sec. at 71 atm. and rises steeply thereafter to 330 m. per sec. at 90 atm.

The equations thus far presented involve no dependence of velocity on the frequency of sound waves. This corresponds to experience as far as the so-called permanent gases are concerned at ordinary pressure and low frequencies; they show no dispersion. As the frequency-pressure ratio increases, however, all gases will show dispersion; indeed, the velocity is found to increase with increasing ν/p. Thus for hydrogen, c increases about 8% from its low-frequency standard-pressure value of 1,284 m. per sec. as ν/p is raised from 1 Mc. per atm. to 30 Mc. per atm.

The velocity of sound waves also depends on the purity of the gas. Small traces of foreign gases can produce significant changes in c. Thus for pure carbon dioxide (with only a trace of neon and argon) the velocity for $v/p = 3.2 \times 10^4$ cycles per atmosphere corresponds to a value of γ in equation (18) of approximately 1.34. With the addition of 2.8% water vapour, however, this same value of γ is associated with $v/p = 1.6 \times 10^6$ cycles per atm. The whole dispersion curve is thus displaced. Alternatively put, the sound-wave velocity at a given v/p value is much decreased by the addition of the water vapour. The velocity is affected, of course, by the motion of the medium. Thus in the open air with the wind blowing the velocity of the wave with respect to the ground will be greater with the wind than against it.

Equation (13) can still indicate the velocity of sound waves in liquids but necessarily uses the adiabatic bulk modulus or compressibility. The change in compressibility of a liquid with temperature is much more complicated than that of a gas; this effectively bars the development of helpful general formulas. Water has been carefully studied and the following equation (G. W. Willard) represents rather accurately the dependence of velocity in metres per second on temperature in degrees centigrade

$$c_t = 1{,}557 - 0.0245(74 - t)^2 \tag{25}$$

This indicates that c_t increases with temperature up to a maximum value at $t = 74°$ C, and thereafter decreases. For practically all other liquids that have been studied c decreases with temperature over the whole range in which the material can stay liquid. Salt solutions obey a rule like equation (25) with different values of temperature for maximum c_t. The case of sea water is complicated by changes in salinity, temperature, and pressure (with depth in the ocean) that are effective in changing velocity. The following empirical formula (L. E. Kinsler and A. R. Frey) holds fairly

well over the range of variables usually encountered

$$c_t = 1.41 \times 10^5 + 4.21 \times 10^2 t - 3.7t^2 + 1.1 \times 10^2 S + 1.8 \times 10^{-2} d \quad (26)$$

where t is in degrees centigrade, S is the salinity in parts per 1,000, and d is the depth in centimetres. The velocity is given in centimetres per second.

As is suggested by equation (26), sound-wave velocity in solutions is markedly dependent on the concentration of the solute. For NaCl, for example, the velocity in a 10% solution at room temperature is 1,600 m. per sec. while for a 20% solution it rises to 1,720 m. per sec. Not all solutions yield higher velocity than does the pure solvent, however.

Equation (26) also indicates that increase in pressure on a liquid raises the velocity more or less linearly. Thus for benzene P. Biquard found that the velocity is increased by about 17% in going from atmospheric pressure to 500 atm.

Unlike the situation in gases, no definite indication of sound-wave dispersion in liquids has been found experimentally, though theoretical considerations suggest it for sufficiently high frequencies, probably of the order of several hundred megacycles.

4. Wave Fronts.—The concept of wave front was introduced earlier to describe the propagation of acoustic waves. Equation (3) dealt with harmonic wave functions corresponding to propagation along the positive x axis only. But since it is the general tendency for sound waves in free space to spread in all directions the analysis must be generalized. To simplify wave propagation in three-dimensional space, the excess pressure is used as the measure of the acoustical disturbance. Consider the function

$$p_e = A(x, y, z) \sin \omega[t - \psi(x, y, z)/c_0] \quad (27)$$

in which A is the amplitude of the pressure wave and may be a function of position in space. The function $\psi(x, y, z)$ is assumed to have the dimensions of distance only, and c_0 is a constant having the dimensions of velocity.

Equation (27) is a genuine harmonic wave function (*i.e.*, a solution of the general three-dimensional equation [7] under certain conditions). The phase of the wave $\omega[t - \psi(x, y, z)/c_0]$ has the constant value ωt_0 at the time t over the surface with the equation

$$\psi(x, y, z) = c_0(t - t_0) \quad (28)$$

Hence this is the general equation for the wave front at time t. In the passage of time the wave-front equation will alter just as if the front itself were moving through space, carrying with it the same value of the disturbance. If

$$\psi(x, y, z) = \alpha x + \beta y + \gamma z \quad (29)$$

equation (28) represents a plane wave front with the direction cosines of the normal to the front equal to α, β, γ. In this case $A(x, y, z)$ reduces to a constant. If

$$\psi(x, y, z) = \sqrt{x^2 + y^2 + z^2} \quad (30)$$

equation (28) represents a spherical wave front. Equation (27) is then a harmonic pressure wave spreading out of the origin if $A(x, y, z) = A_0/r$, where

$$r = \sqrt{x^2 + y^2 + z^2} \quad (31)$$

and A_0 is constant.

Such fronts are somewhat idealized; a spherical wave front demands an obviously nonexistent precise point source of sound. A plane wave front demands an infinitely extended plane source, likewise not achievable. Nevertheless empirical wave fronts often approximate these ideal types sufficiently well to justify their use. In general the smaller the dimensions of a source compared with the wavelength the more nearly the front approximates spherical or hemispherical shape. The larger the dimensions of a plane source compared with the wavelength, the more nearly is a plane wave front realized.

5. Sound Rays; Refraction.—For many purposes the propagation of light can be effectively studied in terms of rays—curves that are always perpendicular to the family of wave fronts associated with a particular propagation. The ray concept is also useful in acoustics but only if the wavelength is sufficiently small; more accurately, if the change in wavelength (due to change in velocity from one point to another in the medium) over a distance of the order of one wavelength is very small compared with the wavelength itself (*see* OPTICS).

Moreover, the ray must not bend too rapidly as the sound wave progresses, and the change in amplitude over a like distance must be small compared with the initial amplitude. If these conditions are satisfied, it is meaningful to write the differential equations of the ray paths in any medium in which the wave velocity c varies from point to point. By analogy with optics it is customary to define the ratio c_0/c as the index of refraction n of the medium. The physical meaning of c_0 is the nonvarying velocity in some homogeneous medium bounding the given nonhomogeneous medium. Let the direction cosines of the ray path be α, β, γ. These are in general functions of position; *i.e.*, of the coordinates x, y, z. If ds is the element of distance along the ray, the differential equations of the ray paths take the form

$$d(\alpha n)/ds = \partial n/\partial x,\ d(\beta n)/ds = \partial n/\partial y,\ d(\gamma n)/ds = \partial n/\partial z \quad (32)$$

As soon as n is known as a function of x, y, z, equations (32) can be integrated to give the rays. As an illustration, suppose n is a constant, so that there is no variation of acoustic velocity in the medium. Equations (32) then lead to

$$\alpha = K_1, \beta = K_2, \gamma = K_3 \quad (33)$$

where K_1, K_2, K_3 are constants, giving then the direction cosines of a straight line. The rays are straight lines, irrespective of the character of the wave fronts (the latter, for example, may have the form of plane or spherical wave fronts).

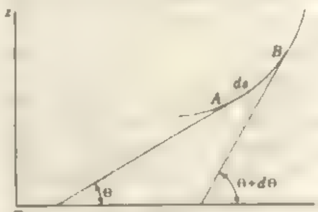

FIG. 3

A typical case of ray propagation occurs when the medium is stratified; *i.e.*, the change in velocity takes place in one direction only, for example, the z axis. It will be sufficient to consider the ray path in the xz plane. In fig. 3 let AB be the element ds of the ray and let the tangents at A and B, respectively, make the angles Θ and $(\Theta + d\Theta)$ with the x axis. Thus

$$\partial n/\partial x = \partial n/\partial y = 0$$
$$\alpha = \cos \Theta, \beta = 0, \gamma = \sin \Theta$$

Equations (32) now yield

$$d(n \cos \Theta)/ds = 0,\ d(n \sin \Theta)/ds = dn/dz \quad (34)$$

The first equation shows that along the ray

$$n \cos \Theta = \text{constant} = n_1 \cos \Theta_1 \quad (35)$$

where Θ_1 is the direction of the ray at the place where the index is n_1. If $\Phi = \pi/2 - \Theta$, where Φ is the angle the ray makes with z, equation (35) becomes

$$\sin \Phi/\sin \Phi_1 = n_1/n = c/c_1 \quad (36)$$

This has the familiar form of Snell's law for the refraction of light rays (*see* REFRACTOMETER). Here, however, it is of much more general form since the variation of velocity is continuous and does not take place abruptly at a boundary plane as in the usual elementary optical case. The abrupt change involves a discontinuity in n and therefore demands special treatment, discussed in section II.7. The second of equations (34) makes possible the evaluation of the curvature $(d\Theta/ds)$ of the ray at any point and hence the equation of the ray path. By straightforward analysis

$$d\Theta/ds = -dc/dz \cdot \cos \Theta_1/c_1 \quad (37)$$

As an illustration, suppose

$$c = c_1 + az \quad (38)$$

i.e., the velocity is a linear function of the depth z (a is a constant), with c_1 = velocity at $z = 0$; this might be the surface of the sea. Then equation (37) shows that the curvature is constant

This means that the path must be a circle with radius $|c_1/a \cos\Theta_1|$. If a is positive, the velocity increases with depth, the curvature is negative, and the path bends upward toward the surface $z = 0$. If a is negative the velocity decreases with depth (a more common situation in the ocean) and the circular path bends downward. These results can readily be followed graphically.

6. Refraction in a Moving Medium.—The propagation of sound waves through a moving medium (*e.g.*, the atmosphere with the wind blowing) is extremely complicated and its analysis will not be given here. However, the law of refraction for a stratified medium turns out to be a rather simple modification of the Snell's law equation (36). If the velocity of the medium is confined to the x direction only and is equal to u, which is a function of z (*e.g.*, height above the ground, taken as the xy plane, in the case of transmission through the atmosphere), the law of refraction becomes

$$c/\cos\Theta - c_1/\cos\Theta_1 = u_1 - u \qquad (39)$$

Here u_1 is the medium velocity at the point where the sound velocity is c_1 and the ray direction is given by Θ_1. Equation (39) reduces to equation (36) for $u = u_1 = 0$. From equation (39) and also from relatively simple graphical constructions the effect of the motion of the medium is seen to bend the wave front and ray in the direction in which the motion takes place. Thus if wind velocity increases upward from the ground, sound wave fronts are lifted to windward and depressed to leeward. This tends to decrease the range to windward and increase it to leeward. These considerations were once of considerable importance in the acoustical detection of aircraft, but were superseded by radar. They remained important in sonic gun ranging.

7. Huygens' Principle; Reflection and Refraction at an Interface.—The propagation of an acoustical wave front through a medium can also be studied by means of a principle developed by Christiaan Huygens (1629–1695). According to this principle, in its elementary form, each point on a wave front (like F_1 in fig. 4, for example) may be assumed to be the source of a hemispherical wavelet which moves outward from F_1 in the direction of propagation; the new wave front after a short time is the mathematical envelope of all these wavelets; *e.g.*, F_2 in the figure. This principle can be demonstrated by considering the solution of the general wave equation. A simple illustration is the establishment of the laws of reflection and refraction at a plane interface separating fluid media with different properties; *e.g.*, different mean densities and sound velocities.

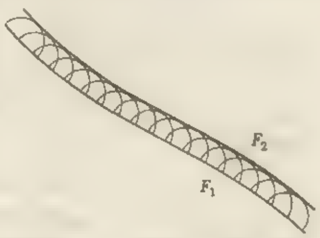

FIG. 4

Let AB in fig. 5 represent the trace in the plane of the paper of the plane interface between a fluid medium I in which the velocity of sound is c_1 and the mean density is ρ_1, and a medium II in which the corresponding quantities are c_2 and ρ_2, respectively. Let CD denote the trace of a plane wave front (perpendicular to the plane of the paper) incident on AB at angle Θ_i. This means that the incident ray travels in the direction HC perpendicular to CD. The reflected and refracted wave fronts can be constructed by means of Huygens' principle. At the instant the disturbance at one end of the wave front has reached C on the interface, the disturbance at the other end is still at D in medium I. In the time $t_1 = DE/c_1$ that it takes the disturbance at D to reach E on the interface, the disturbance will travel out in all directions from C. In particular in I it will traverse a distance equal to DE.

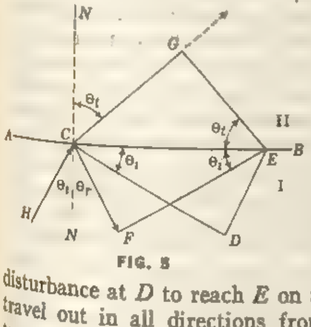

FIG. 5

If (with C as centre) a semicircle is drawn in medium I with radius DE, and a straight line from E is constructed tangent to this, it produces FE which makes the angle $\Theta_r = \Theta_i$ with AB. That this is the reflected wave front can be confirmed by making a Huygens construction for other points on the incident wave front. It is seen that the reflected wave front makes the same angle with the interface as the incident wave front. This, combined with the fact that both wave fronts are perpendicular to the same plane (the plane of the paper), constitutes the law of reflection. Equally well expressed in terms of the incident and reflected rays, it is the same law that holds for light-wave fronts and rays.

The same kind of analysis shows that after transmission across the interface the incident wave front CD is changed to the refracted wave front GE making the angle Θ_t with AB, such that

$$\sin\Theta_t/\sin\Theta_i = c_2/c_1 = n_{21} \qquad (40)$$

This is Snell's law again, with n_{21} the index of refraction of medium II with respect to medium I. If the media are in motion with respect to each other, this result must be modified (*cf.* equation [39]). Equation (40) accounts well for the passage of sound waves from air to water or vice versa.

8. Energy Propagation; Intensity.—Sound-wave propagation is basically a form of transmission of energy through a medium. When a fluid, for example, is compressed, work is done, representing the expenditure of energy. The reappearance of the disturbance at a distant point by wave propagation corresponds to the transfer of the original energy. The greater the amount of energy transported per unit area of wave front per unit of time, the greater will be the intensity of the sound wave.

To be more precise, the rate of flow of energy in the sound wave per unit time per unit area of wave front is simply calculated as the average of the product of the excess pressure p_e and the flow velocity $\partial\xi/\partial t$ in the medium. Analysis shows that the intensity I of a plane wave computed in this way can be expressed as

$$I = p_0^2/2\rho_0 c \qquad (41)$$

This important formula (G. W. Stewart and R. B. Lindsay) shows that the intensity of a plane wave is equal to the square of the excess pressure amplitude p_0 divided by twice the product of mean density and sound-wave velocity. Significantly it is independent of frequency.

The standard absolute unit of intensity is the erg/sec-cm^2. More practical is the watt/cm^2 or, in the metre-kilogram-second systems, the watt/metre^2. However, the decibel (commonly used as the standard unit of sound intensity) is a relative measure. If two sound waves have absolute intensities I_1 and I_2 respectively they are said to differ in intensity level by D decibels (or db.), where

$$D = 10 \log_{10} I_2/I_1 \qquad (42)$$

Hence if $I_2 = 2I_1$, $D = 3.01$ db., or doubling the intensity means an increase of intensity of a little more than 3 db. To use this method of measuring intensity requires the choice of a standard level. This is often taken as that corresponding to an average excess pressure of 1 dyne/cm^2 in air (close to the normal level for conversational speech). The minimum audible stimulus lies about 70 db. below this level, while the threshold at which the stimulus becomes painful lies about 70 db. above this level. These figures are approximate and depend on frequency. In modern acoustical practice the reference level is almost always taken at the average human threshold for hearing, corresponding to root-mean-square acoustic excess pressure 2×10^{-4} dyne/cm^2 or intensity 10^{-16} watt/cm^2.

From equation (41) it is clear that intensity at given pressure depends on the medium and in particular on the product $\rho_0 c$. This quantity is known as the specific acoustic resistance of the medium (for a plane wave). For water, for example, it is about 3,800 times the value for air at standard pressure. Consequently the same excess pressure in water produces a much lower intensity than in air, at first glance suggesting that it is harder to produce an intense sound wave in water than in air. However, at given frequency and pressure a solid radiating source is empirically more efficient in water (and in liquids generally) than in air.

9. Intensity of Spherical Waves.—Equation (41) was cited as applying to a plane wave. A similar formula applies to a spherical wave in the corresponding medium, but the pressure and particle velocity expressions are different. Whereas for a plane

wave the excess pressure and flow velocity (sometimes called particle velocity) amplitudes are constant in a nonabsorbing medium, for a spherical wave they both fall off with the distance from the source of the radiation. Multiplication and averaging, as in section II.8 above, yields for the intensity in the spherical wave at distance r from the source

$$I = p_0^2/2\rho_0 c r^2 \tag{43}$$

Equations (41) and (43) can be put in the same form by writing

$$I = \overline{p_e^2}/\rho_0 c \tag{44}$$

where $\overline{p_e^2}$ is the average of the square of the excess pressure at the point where the intensity is computed.

10. Flow of Energy Across a Boundary.—Recall that when a sound wave strikes the interface separating two media with different physical properties (*e.g.*, going from air to water or vice versa) some of the wave is reflected while the rest is transmitted (and in general refracted). This means that the transmission of acoustic energy is affected by the presence of the boundary.

In fig. 6, OA denotes the plane boundary separating media I and II, the x axis being perpendicular to the boundary. In medium I the mean equilibrium density is ρ_1 and the wave velocity is c_1. The corresponding quantities in medium II are ρ_2 and c_2. The arrow i denotes a plane harmonic sound wave traveling in I from left to right in the x direction and striking the boundary at $x = 0$. Similarly r denotes the wave in I reflected from the boundary and t denotes the wave transmitted into medium II across the boundary. For simplicity assume perpendicular incidence. Let the amplitude of the excess pressure in the incident wave be p_i, that in the reflected wave p_r, and that in the transmitted wave p_t. By setting up two algebraic relations connecting these three quantities, the reflected and transmitted pressure amplitudes can be expressed in terms of the incident; by doing the same for the particle velocity amplitudes, the relative amount of transmitted and reflected energy can be estimated.

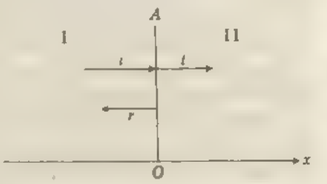

FIG. 6

These two relations are called the boundary conditions at the interface. They specify that there must be no discontinuity in the excess pressure and particle velocity at the boundary. Otherwise put, the sum of the pressure amplitudes of the incident and reflected waves at the boundary must equal the transmitted pressure amplitude, and similarly for the particle-velocity amplitudes. The result of applying these two conditions is

$$\frac{p_r}{p_i} = \frac{1 - \rho_2 c_2/\rho_1 c_1}{1 + \rho_2 c_2/\rho_1 c_1} \tag{45}$$

and

$$\frac{p_t}{p_i} = \frac{2}{1 + \rho_1 c_1/\rho_2 c_2} \tag{46}$$

Use of equation (41) yields for the power transmission ratio P_r of the intensity in the transmitted wave to that in the incident wave

$$P_r = I_t/I_i = \frac{4\rho_2 c_2/\rho_1 c_1}{(1 + \rho_2 c_2/\rho_1 c_1)^2} \tag{47}$$

It will be noted that P_r depends wholly on $\rho_2 c_2/\rho_1 c_1$, or the ratio of the specific acoustic resistances of the two media. If the resistances are equal in spite of the boundary, then $P_r = 1$; for any other ratio $P_r < 1$. The specific acoustic resistance ρc therefore controls the transmission of energy at normal incidence from one medium to another. If the boundary is between a gas and a solid, the large difference between the ρc values for the two will give a small P_r, suggesting that in this case the reflection coefficient (ratio of reflected to incident intensity) will be high. The reflection coefficient R is given by

$$R = 1 - P_r = \left(\frac{1 - \rho_2 c_2/\rho_1 c_1}{1 + \rho_2 c_2/\rho_1 c_1}\right)^2 \tag{48}$$

Equations (47) and (48) account adequately for the observation that transmission from air to water or from air to a solid wall is relatively poor, with reflection correspondingly high. For air-to-water transmission the value of P_r is only 0.12%.

In considering the more general case of oblique incidence, recall that Snell's law describes the geometrical refraction associated with oblique transmission. The power transmission ratio now depends on the angles of incidence and refraction Θ_i and Θ_t respectively. Thus

$$P_r = \frac{4\rho_2/\rho_1 \cdot \cot\Theta_t/\cot\Theta_i}{(\rho_2/\rho_1 + \cot\Theta_t/\cot\Theta_i)^2} \tag{49}$$

It is to be noted that P_r here is the actual ratio of transmitted power (*e.g.*, watts) to incident power. It is not the ratio of transmitted intensity (*e.g.*, watts/cm²) to incident intensity. To obtain the latter, P_r is divided by the ratio S_t/S_i, where S_i and S_t are respectively the areas of the incident and transmitted wave fronts. From fig. 5

$$S_t/S_i = \cos\Theta_t/\cos\Theta_i \tag{50}$$

In practice P_r is in general the more important quantity. The reflection coefficient R in this case (the wave fronts are here equal in area) can be calculated as in equation (48) and becomes

$$R = 1 - P_r = \left(\frac{\rho_2/\rho_1 - \cot\Theta_t/\cot\Theta_i}{\rho_2/\rho_1 + \cot\Theta_t/\cot\Theta_i}\right)^2 \tag{51}$$

When $\Theta_i = 0$ (normal incidence), equation (51) reduces to equation (48). When $\Theta_i = 90°$ (grazing incidence) then $P_r = 0$ and there is complete reflection. If $c_2 > c_1$ total reflection ensues for angles of incidence greater than the critical angle Θ_c, where

$$\Theta_c = \text{arc sin } c_1/c_2 \tag{52}$$

in complete analogy with geometrical optics. On the other hand, there is complete transmission and no reflection if

$$\cot\Theta_t/\cot\Theta_i = \rho_2/\rho_1 \tag{53}$$

This takes place for angle of incidence Θ_i such that

$$\cot^2\Theta_i = \frac{c_1^2/c_2^2 - 1}{\rho_2^2/\rho_1^2 - c_1^2/c_2^2} \tag{54}$$

demanding

$$\rho_2/\rho_1 > c_1/c_2 > 1 \text{ or } \rho_2/\rho_1 < c_1/c_2 < 1 \tag{55}$$

There are important applications of these formulas to transmission in the atmosphere between layers of air at different temperature and humidity, and to transmission in sea water with temperature gradients.

11. Impedance.—The importance of the product ρc (usually written $\rho_0 c$) in transmission of a plane wave between media is emphasized by its name (specific acoustic resistance).

Inevitably this suggests an electrical analogy. It is readily verified that the ratio of the excess pressure to the flow or particle velocity in a plane progressive acoustic wave in a fluid is $\rho_0 c$. In the case of direct currents in electricity, the ratio of potential difference to current flow is called the resistance of a conductor. Consider acoustic excess pressure as analogous to potential difference and acoustic particle velocity as analogous to electric current: the significance of acoustic resistance then becomes clear. Since acoustical quantities vary with time and space (sinusoidally in the most commonly used cases) it appears more relevant to make the analogy with alternating electric current. In the latter the ratio of alternating potential difference (or electromotive force, emf) to alternating current is called the electrical impedance. Moreover $\frac{\partial \xi}{\partial t}$ appears in the guise of an acoustic current density; to generalize

$$p_e/\frac{\partial X}{\partial t} = Z = \text{acoustic impedance} \tag{56}$$

where $\frac{\partial X}{\partial t} = S\frac{\partial \xi}{\partial t}$, the so-called acoustic volume current, S being the area of the acoustic wave front.

In alternating current theory the impedance Z is in general made

up of a resistive component and a reactive component; the resistive component yields the part of the current that is in phase with the alternating emf and the reactive component the part of the current that is out of phase with the emf by 90°. For an alternating current circuit containing resistance R in series with inductance L and capacitance C, the ratio of the amplitude of the applied electromotive force to the amplitude of the resulting current is

$$Z = \sqrt{R^2 + (\omega L - 1/\omega C)^2} = \sqrt{R^2 + \chi^2} \tag{57}$$

where ω ($= 2\pi\nu$) is the angular frequency of the current and χ is equivalent reactance. The current lags behind the emf by the phase angle

$$\alpha = \arctan\left(\frac{\omega L - 1/\omega c}{R}\right) = \arctan\frac{\chi}{R} \tag{58}$$

This electrical theory applies to oscillations, while the acoustical analogy concerns waves. There is no phase lag between excess pressure and volume current in a plane acoustic wave. Hence the corresponding phase angle in this case is zero. This means that the equivalent acoustic reactance vanishes and the acoustic impedance is a pure resistance; hence the name acoustic resistance for $\rho_0 c/S$. Calling $\rho_0 c$ itself the specific acoustic resistance (denoted by Z_s) also follows electrical analogy, since the specific electrical resistance of a conductor is the resistance per unit length and for unit area of cross section.

Though the specific acoustic impedance of a plane wave is a pure specific resistance, this does not hold for a spherical wave, which has both reactive and resistive components in its impedance. The physical meaning of this is connected with the spreading of the wave in all directions. The reactance of a diverging spherical wave is positive and behaves like an electric inductance, whereas the reactance of a spherical wave converging to a point is negative and thus behaves like an electric capacitance.

The impedance notation permits acoustic transmission calculations to be replaced to advantage by analogous electrical computations. Many acoustical effects can be readily estimated in terms of known values of acoustic impedance at strategic points. For example, the effectiveness of a horn (*i.e.*, a tube of variable cross section) both as a receiver and a transmitter of sound waves is measured (for given volume current) by the value of the acoustic resistance at the throat. The effective acoustic transmission through a tube in which a branch line is inserted at some point can be shown to depend in a relatively simple manner on the acoustic impedance at the branch point. Problems in architectural acoustics involving the reflection of sound from the walls of a room can often be simplified by the use of the impedance notation.

12. Selective Transmission; Filtration.—The transmission of acoustic energy in a harmonic wave across the interface separating two media is independent of frequency as equations (47) and (49) indicate. Here both media have been considered semi-infinite (medium I infinite to the left of the interface and medium II infinite to the right). A different situation arises if one of the media is finite in the direction of wave travel.

In fig. 7 let medium II, of length l, be inserted between media I and III, which are semi-infinite. The mean densities in the three media are ρ_1, ρ_2, ρ_3 respectively and the corresponding sound velocities are c_1, c_2, c_3.

FIG. 7

The analysis of section II.10 above may then be applied, remembering that because of the reflections at interfaces 1 and 2 there will be waves traveling in both positive and negative directions in medium II, even though the radiation comes from the left in I and goes to the right in III. Use of the appropriate boundary conditions as before gives for the power transmission ratio P_r (ratio of transmitted power in III to incident power in I) for normal incidence

$$P_r = \frac{4R_3/R_1}{(R_3/R_1+1)^2} \cdot \frac{1}{1 - \dfrac{(R_3^2/R_2^2-1)(R_2^2/R_1^2-1)}{(R_3/R_1+1)^2} \cdot \sin^2 k_2 l} \tag{59}$$

In this expression R_1, R_2, R_3 are the specific acoustic resistances of media I, II, III respectively, and $k_2 = \omega/c_2$. The dependence of P_r on the frequency arises through the term $\sin^2 k_2 l$. The effect can be seen most simply for the special case in which $R_1 = R_3$; *i.e.*, the third medium is the same as the first. Then (now denoting the power transmission ratio by P_r')

$$P_r' = \frac{1}{1 - \dfrac{(2 - R_2^2/R_1^2 - R_1^2/R_2^2)}{4}\sin^2 k_2 l} \tag{60}$$

If $\sin^2 k_2 l = 0$, $P_r' = 1$. If $\sin^2 k_2 l = 1$, P_r' passes through the minimum value $4/(2 + R_2^2/R_1^2 + R_1^2/R_2^2)$, which is the smaller, the greater the difference between R_1 and R_2. The plot of P_r' as a function of frequency then appears as in fig. 8.

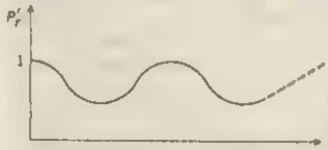

FIG. 8

The transmission is said to be selective with respect to frequency, with the frequencies $\nu_n = nc/2l$, where n is integral, yielding 100% transmission, and the frequencies $\nu_n = (2n+1)c/2l$ yielding minimum transmission. In no case does the value of P_r' become precisely zero. The situation may be described by saying that the medium II acts as if it preferred to have harmonic waves of frequencies $\nu_n = nc/2l$ traveling back and forth in it and would not tolerate others so readily.

This suggests the possibility of arranging a collection of media that will act as an acoustic filter; *i.e.*, transmit waves of certain frequencies well but fail entirely to pass waves of other frequencies. If this could be realized the curve of P_r against frequency ν would appear, for example, as in fig. 9. The transmission here has unit value between *0* and *A*, *B* and *C*, *D* and *E*, and so on. These frequency intervals should be called pass bands, whereas since in *AB*, *CD*, and so on, P_r drops to zero, they correspond to attenuation bands.

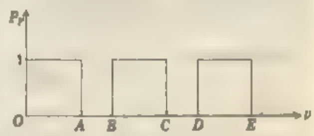

FIG. 9

Theoretical study indicates that a structure with these properties can be approximated by an iteration of two media (fig. 10). The larger the number of pairs in the iteration (or sections of the filter) the more closely will the transmission curve correspond to the sharp alternation of pass and attenuation bands as in fig. 9. In any case the structure is called a low-pass filter, since low frequencies from zero to *A* are passed.

FIG. 10

The type of acoustic filter just discussed depends on the alternation of properties of two different media. This is not necessary to achieve the same general result.

Fig. 11 represents a succession of cylindrical tubes of cross-sectional areas S_1, S_2 and of lengths $AB = CD = EF$, and so on, for the wide tubes and $BC = DE$, and so on, for the narrow tubes. Such a structure acts as a low-pass filter for harmonic sound radiation—the transmission pattern of pass and attenuation bands is very similar to that in fig. 9.

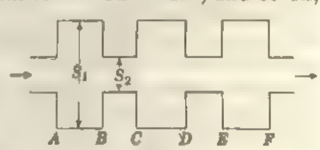

FIG. 11

Here the ratio S_2/S_1 of the cross-sectional areas of the constricted and expanded tubes serves the same role as the ratio of the specific acoustic resistances in the iterated-media filter. The lengths of the sections have a decided bearing on the frequency range of the transmission and attenuation bands. Many other types of acoustic filters have been constructed to suppress certain frequency bands in blowers, mufflers, and other equipment producing noise by the flow of air and other gases. The same type of theory applies to the filtration of elastic waves in solids; *e.g.*, rods. Many musical instruments incorporate acoustical filters.

Selective transmission as discussed in this section does not arise from a genuine frequency-dependent absorption with transforma-

tion of acoustic energy into heat. The filtration results when waves of certain frequency ranges are effectively barred; *i.e.*, not accepted from the source.

13. Absorption and Dispersion in Fluids.—The decrease in intensity from a localized source (*i.e.*, approximately at a point) because of spherical spreading fails to account for the total loss in intensity. The additional loss is manifested even when waves pass through a more or less homogeneous medium in which there is no selective transmission or filtering. Such loss is ascribed to absorption of the sound energy and its transformation into heat. An obvious source of such absorption is the internal friction of the medium through which the radiation passes. This friction is exemplified by the so-called shear viscosity of a fluid, which is a measure of the tendency of relative motion of adjacent layers of the fluid to be decreased (*see* VISCOSITY). For the simplest type of viscous fluid (*e.g.*, air and water) the shearing stress or drag per unit area of parallel layers of fluid on each other is directly proportional to the rate of change of the flow velocity (assumed parallel to the layers) with respect to distance normal to the flowing layers; the coefficient of proportionality is called the shear viscosity η.

Analysis shows that for a plane harmonic acoustic wave of angular frequency ω progressing in the x direction in a viscous medium the displacement ξ can be written

$$\xi = \xi_0 e^{-\alpha x} \cos (\omega t - kx) \tag{61}$$

in which α is known as the amplitude absorption coefficient. It represents an exponential decrease in the amplitude of the wave with distance traveled, corresponding to the absorption of the acoustic energy by the medium. Expressed in terms of the viscosity of the medium and the frequency, the absorption coefficient can be written

$$\alpha = \omega^2 \tau V/2c^2 (1 + \omega^2\tau^2) \tag{62}$$

where

$$V = \sqrt{2}c/\omega\tau \cdot [(1 + \omega^2\tau^2) (\sqrt{1 + \omega^2\tau^2} - 1)]^{\frac{1}{2}} \tag{63}$$

and

$$\tau = 4\eta/3\rho_0 c^2 \tag{64}$$

Here $V = \omega/k$ is the phase velocity of the wave. The fact that V in equation (63) depends on the frequency indicates dispersion of the wave. This recalls that the velocity of light in matter normally decreases as the frequency increases. From equation (63) it is seen that at zero frequency $V = c = \sqrt{B/\rho_0}$, where B is the adiabatic bulk modulus of the fluid, and as ω increases, V increases. For real fluids, even with considerable viscosity (*e.g.*, glycerol with $\eta = 5$ poises at room temperature), the value of τ (often referred to as a relaxation time) is extremely small and hence $\omega\tau$ is negligibly small compared with unity except for extremely high frequencies. Equations (62) and (63) for α and V do not in themselves account for the observed acoustic absorption and dispersion in fluids even at low frequencies. Other mechanisms enter into the attenuating process.

Another obvious basis for acoustic absorption in fluids is the conduction and radiation of heat. In the passage of a compressional wave the temperature is increased at points of maximum excess density (condensation). In the simple theory of wave-energy propagation set forth earlier, the heat energy corresponding to this temperature (strictly extra kinetic energy of the molecules of the fluid) is passed on to the adjacent portion of the fluid to produce a corresponding compression there. This neglects heat conduction and radiation to the surroundings. Some of the energy that is necessary to propagate the disturbance gets lost in transit, effectively corresponding to absorption of the sound wave. The complicated analysis shows that the absorption coefficient due to the combined effects of viscosity and heat conduction at not-too-high values of the ratio of frequency to pressure (*i.e.*, less than 1,000 Mc. per atm.) becomes

$$\alpha = 2\pi^2\nu^2/\gamma p_0 c \cdot [4\eta/3 + (\gamma - 1)\kappa/c_p] \tag{65}$$

where ν is the actual frequency, p_0 the mean equilibrium pressure, c_p the specific heat at constant pressure, κ the thermal conductivity, γ the ratio of the specific heat at constant pressure to that at constant volume, and the other symbols have their previously assigned meanings. The two terms in the brackets in equation (65) correspond to the contributions of viscosity and heat conduction respectively. Analysis shows that for monatomic gases the contribution of heat conduction to α is about 70% that due to viscosity. The ratio of the heat conduction to the viscosity contribution is approximately $\gamma - 1$, so that for polyatomic gases the heat conduction contributes relatively much less.

For liquids other than mercury and liquefied gases the contribution of heat conduction is such a small fraction of that due to viscosity that it may be neglected. The part played by radiation in gases and liquids is negligible except possibly at very low pressures or very high temperatures.

Equation (65), the so-called classical absorption formula, agrees very well with experimental values for monatomic gases (*e.g.*, helium, argon). The more precise formula of which this is an approximation has been found to agree in the case of helium down to pressures of the order of 1 mm. of mercury and up to frequencies of 1 Mc. However, for diatomic and other polyatomic gases and liquids there are some frequency regions in which the absorption is much greater than that predicted. For the vast majority of liquids the absorption over wide frequency ranges is found experimentally to vary more or less as the square of the frequency as equation (65) indicates. However, the experimental values are almost uniformly in excess of those predicted. Thus α/ν^2 for water at room temperature over the range from 1 to 50 Mc. is about 25×10^{-17} sec^2 cm^{-1}, whereas the formula yields only 8.5×10^{-17} sec^2 cm^{-1}. The discrepancy is even greater (approaching a factor of 100 or more) for many organic liquids like benzene.

Such deviations have led to alternative theoretical postulations for acoustic absorption. One of these is based on the idea that when a fluid is compressed in the passage of a wave the work done does not merely increase the average translational velocity of the molecules; some of it, through molecular collisions, enters into other states of energy; *e.g.*, rotational and vibrational in the case of diatomic and other polyatomic molecules. Calculation shows that there is a lag (relaxation time) in this process of energy transfer; *i.e.*, a given average time is required for the energy to come back to translational form after it has become rotational or vibrational. Because of this lag the changes in translational energy of the molecules fail to keep in step with the propagation of the wave; thus some of the original energy of the disturbance is made unavailable during each cycle for transmission. It is therefore lost in dissipation and the result is effectively absorption. Shear viscosity can be considered a kind of relaxation process and the corresponding relaxation time is the τ given by equation (64). It is evidently not an adequate mechanism. In the case of polyatomic gases vibrational (and to some extent rotational) relaxation has proved useful in accounting for the observed excess absorption. This type of relaxation is usually termed thermal, since it corresponds effectively to an apparent increase in specific heat (*see* RELAXATION PHENOMENA).

If a thermal relaxation process is at work in a gas, when the product of absorption coefficient α and wavelength λ is plotted against the frequency, the result is a curve that rises to a maximum and then falls off again. The frequency at which the maximum occurs is called the relaxation frequency and is equal to $1/2\pi\tau$, where τ is the relaxation time. Acoustic absorption measurements in gases thus serve to indicate the presence of a relaxation effect and to evaluate τ. In many gases the relaxation frequency was found in the ultrasonic range. For example, for hydrogen it is 10 Mc. at 1 atm. For lower pressures it is proportionally reduced. Measurements of relaxation frequency have shed light on the internal energy states of gas molecules, especially on the probability of transitions between these states, a quantity proportional to the reciprocal of the relaxation time.

These acoustic-absorption measurements can also be of value in engineering. In the high-speed flow of gases and vapours on obstacles (*e.g.*, steam against turbine blades), sudden compressions and rarefactions are accompanied by temperature changes. The time during which such changes take place is controlled by

the dimensions of the obstacles and the flow velocity. If the time interval is of the same order as the relaxation time for transitions to and from internal energy states of the gas molecules, translational energy will be lost (similar to acoustic absorption in the gas) with a measurable decrease of impact pressure on the obstacle. Acoustical measurement of the relaxation time in the relevant pressure and temperature range is the best way to estimate the likelihood of this process.

Absorption with regard to liquids is not so satisfactory theoretically as for gases. For many organic liquids (*e.g.*, benzene and carbon tetrachloride) the excess absorption over that provided by classical viscosity and heat conduction can probably be accounted for by thermal relaxation. This is, however, not the case for water. A theory due to L. H. Hall assumes that molecules of water can take on two kinds of arrangement. In one they are arranged more or less tetragonally as in ice; in the other they are packed more closely together (cubic close-packed structure). These arrangements are analogous to states of translational and internal energy of gas molecules and a relaxation theory can be worked out for them. Termed structural relaxation, it implies a kind of relaxational compressibility: the difference between static compressibility as ordinarily measured and so-called instantaneous compressibility corresponding to very high-frequency sound waves. This leads to a compressibility that varies with frequency and hence yields dispersion as well as absorption. By reasonable choice of parameters the theory accounts for the observed excess of absorption over that classically computed and also gives the proper variation of the absorption coefficient with temperature from 0° to 100° C. The predicted dispersion is extremely small and had not yet been measured in the 1960s. Hall's theory was criticized and modified by C. Davis and T. A. Litovitz; however, the fundamental idea of structural relaxation has been confirmed.

Whether the theory of structural relaxation can be applied to water solutions like electrolytes is uncertain. Relaxation caused by chemical dissociation probably plays a role also. As in gases, it is likely that information about the liquid state (the most difficult state to understand) could be gained from study of absorption and dispersion mainly in the ultrasonic range. Efforts to use relaxation mechanisms in accounting for acoustic absorption in solutions of electrolytes increased in the 1960s (led by E. Yeager in the U.S.).

The relaxation-time theory of acoustic absorption in liquids has suggested the concept of bulk or volume viscosity. This is associated with a resistance related to the rate of volume compression as the more common shear viscosity is related to the rate of shearing strain. According to Hall's theory this bulk viscosity for water is several times as great as the shear viscosity. It decreases as the temperature increases. A bulk viscosity of this magnitude corresponds to a very high relaxation frequency; in water, for example, of the order of 10^{12} cycles/sec and hence outside the range of direct experiment.

Wave dispersion in fluids is basically a high-frequency (ultrasonic) phenomenon. More strictly, in gases it appears at large ratios of frequency to pressure; *i.e.*, it has been observed at relatively low frequencies (though not in the audible range) if the pressure is low enough. However, dispersion is a second-order phenomenon compared with absorption; that is, wave velocity differs from its value $c = \sqrt{\gamma p/\rho}$ in the simple classical theory only by terms of the order $c\omega^2\tau^2$, whereas the absorption coefficient depends on the first power of τ. This is clear from equations (62) and (63) for the case of shear viscosity, and the result is not materially different in the case of relaxation absorption and dispersion. Hence dispersion due to relaxation may be more difficult to detect than the associated absorption.

Acoustic dispersion in liquids has been particularly difficult to detect experimentally, since the velocity is very sensitive to temperature, and it is hard to keep temperature constant in acoustic transmission. Up to the 1960s no unambiguous case of dispersion in a pure liquid had been exhibited, though dispersion had been measured in liquid suspensions.

Elementary treatments of wave propagation assume that liquids (like gases) have no shear elasticity and hence can transmit compressional waves only. This has been the basis for the analysis presented here. However, it is not empirically verified in the case of viscous liquids like polybutylene, gels, and rubber solutions; called viscoelastic substances, they have shear elasticity and can propagate shear waves. Since their effective rigidity modulus increases with the frequency, the velocity of shear waves in this case is also frequency dependent. In polybutylene solutions the rigidity may rise from 3×10^7 dynes/cm^2 at 300 kc. per sec. to 5×10^9 dynes/cm^2 at about a megacycle. The viscosity of such liquids can be determined by acoustical measurements. The relaxation-time concept was profitably applied in the 1960s to account for acoustic absorption in viscoelastic substances, largely through the work of W. P. Mason in the U.S.

Of all liquids, probably liquid helium (*q.v.*) exhibits the most interesting and anomalous properties. Thus below about 2.2° K (its so-called lambda point) it loses practically all shear viscosity and gains high thermal conductivity. This modification is known as helium II and is called a superfluid. Its acoustical characteristics also show anomalies. Above the lambda point acoustic velocity increases as the temperature is lowered, reaching a maximum of 220 m/sec at 2.5° K. It then falls sharply to about 216 m/sec at the lambda point and thereafter rises again as the temperature is lowered, appearing to level off to about 239 m/sec as absolute zero is approached. Acoustic attenuation in liquid helium above the lambda point is explainable in terms of viscosity and heat conduction; no thermal relaxation appears to be involved. However, the attenuation reaches a maximum (for given frequency) at the lambda point and then declines very rapidly to a minimum at 2° K. It then rises again as the temperature is lowered to absolute zero. This peculiar behaviour is evidently due to some kind of unusual relaxation mechanism.

Liquid helium II can transmit a peculiar kind of thermal wave; *i.e.*, pressure and density remain constant throughout the liquids, but a temperature fluctuation is propagated. The velocity of this wave is zero at the lambda point but increases as the temperature falls, reaching a maximum of 20 m/sec at about 1.75° K, and then decreasing again as the temperature is lowered further. This wave phenomenon, first reported by L. D. Landau (*q.v.*), is called second sound, though this is questionable terminology. The source of the thermal radiation is usually a thermophone: a platinum ribbon to which an alternating current is applied, producing a harmonically varying source of heat. The waves are detected by a resistance thermometer. For more information on the properties of helium at low temperatures, *see* LOW-TEMPERATURE PHYSICS.

Liquid helium is a valuable adjunct in low-temperature acoustics, being used as a coolant in transmission studies at very low temperatures, especially in solids.

14. Diffraction and Scattering.—It has been mentioned that when a sound wave strikes an obstacle of finite size some of it is reflected, some is transmitted, and in general some gets around the obstacle (or is diffracted). Because of the obstacle the original sound beam is deflected and the pattern of intensity distribution is altered; it is customary to say that the beam is scattered. The resultant intensity pattern is a superposition of the original beam and the scattered energy due to reflection, transmission, and diffraction.

In theoretically estimating harmonic-wave scattering it is assumed that from the completely rigid obstacle there spreads out in every direction a wave of arbitrary amplitude and phase. When the particle displacement due to this scattered wave is added to that corresponding to the primary undisturbed wave the result must be zero everywhere on the surface of the obstacle. (This is idealized since there apparently is no such thing as a completely rigid obstacle that sound energy cannot penetrate. Nevertheless this approximation is useful for such objects as the human head.) The application of this boundary condition suffices to evaluate the unknown amplitude of the scattered wave and hence to give the scattering pattern. This general method can be applied readily only to obstacles of simple geometrical shape, such as cylinders and spheres. But many obstacles found in practice can be approximated reasonably well by such surfaces.

The scattering pattern depends on the relation between the wave-

length of the primary wave and the dimensions of the obstacle. Consider a sphere of radius a as the obstacle. If the wavelength λ is very small compared with $2\pi a$, the scattered wave on the side of the sphere opposite to the direction of the incident primary wave combines with the latter to produce zero intensity (destructive interference). Hence the obstacle forms a shadow that is sharper the smaller the ratio $\lambda/2\pi a$. Since this is analogous to optical shadows of objects with dimensions much larger than the wavelength of light (the case of geometrical optics), it is part of geometrical acoustics. For audible waves (wavelength in air greater than about 1.7 cm.) this type of scattering is important only for relatively large obstacles. However, for ultrasonic (high-frequency) waves it can be quite significant. Geometrical acoustics in the audible region is not as useful as geometrical optics for visible light, which has a much smaller wavelength.

For the opposite extreme, if the wavelength is very large compared with $2\pi a$, the primary wave is scattered in all directions and there is no distinct shadow. The intensity of the scattered wave is directly proportional to the square of the volume of the scattering particle (in this case a sphere) and inversely proportional to the fourth power of the wavelength. This is the Rayleigh scattering law in acoustics; its optical analogue helps account for the blue colour of the sky (*q.v.*). In the scattered radiation the higher frequencies will produce the high intensities. Sound waves scattered by a grove of trees appear to be raised in pitch. A similar phenomenon results when underwater sound waves are scattered by air bubbles.

The middle range in which the wavelength and the dimensions of the scattering obstacle are comparable is much more difficult to handle computationally. In general the intensity of the scattered radiation at any particular distance from the obstacle goes through a series of maxima and minima as the azimuth is varied. Relatively near the obstacle the diffraction pattern tends to be very complex, resembling the well-known Fresnel pattern in optics. Farther away it reduces to the smoother Fraunhofer diffraction pattern (*see* LIGHT: *Diffraction*).

The special case of diffraction by the human head can become evident to any careful observer. For given audible wavelength the acoustic intensity from a speaker's mouth is greatest directly in front. It falls off at right angles to this but rises again back of the head. This secondary maximum is only comparable with that directly in front at distances large compared with the wavelength. Very close to the head, however, the variation in intensity with azimuth is marked.

The head's effect on sound waves received at the ears is also a well-marked phenomenon. The resultant apparent intensity at the ears is a maximum when the line connecting the ears lies in the direction of the sound and falls in general to a minimum when the direction of the sound lies at right angles to this line.

This result is obtained theoretically by the use of the so-called reciprocal theorem of H. L. F. von Helmholtz (Lord Rayleigh, *Theory of Sound*, vol. ii, para. 294 [1945]): "If in a space filled with air which is partly bounded by finitely extended fixed bodies and is partly unbounded, sound waves be excited at any point A, the resulting velocity potential ϕ at a second point B is the same both in magnitude and phase as it would have been at A had B been the source of sound." Though stated for the velocity potential (equal in acoustic waves to the negative of the time integral of the excess pressure divided by the mean density), the theorem also applies to acoustic intensity and plays an important role in calibrating acoustical instruments for measuring radiation.

15. Waves in Finite Spaces; Standing Waves in a Tube.—Spreading sound waves or waves progressing in one direction only require an infinitely extended medium. If the medium is surrounded by a barrier to produce a closed finite space, reflection tends to occur, producing waves in several directions.

Consider a cylindrical tube, of length l and cross-sectional area S, closed rigidly at both ends. A disturbance anywhere in the air in the tube will be reflected from both ends and produce in general a series of waves traveling in both directions along the tube. From the geometry of the situation and the finite constant value of acoustic velocity, these must be periodic waves with frequencies fixed by the boundary conditions at the ends of the tube; *i.e.*, zero resultant value. The allowed frequencies of the waves in the tube satisfy

$$\sin kl = 0 \tag{66}$$

i.e., the allowed frequencies are

$$\nu_n = nc/2l \tag{67}$$

where n is any integer and c is the acoustic velocity in the tube. These are the frequencies of harmonic waves that can exist in the tube and still satisfy the boundary conditions at the ends. They are called the characteristic frequencies or normal modes of vibration of the air column. The fundamental frequency is

$$\nu_1 = \nu_f = c/2l \tag{68}$$

The higher frequencies, called harmonics or overtones, are multiples of the fundamental. It is customary to refer to the fundamental as the first harmonic; $n = 2$ gives the second harmonic or first overtone, and so on. Approximately the same set of characteristic frequencies hold for a cylindrical tube open at both ends, though the boundary conditions are different. Ideally at the end of such a tube it may be assumed that the acoustic excess pressure remains zero since it is open to the surrounding air. This is by no means obvious since there can readily be nonvanishing excess pressure in a wave progressing through the open air. It could be reasoned that at such an open end there is nothing to check the air displacement along the length of the tube and hence the particle displacement or velocity will be a maximum there. This means $\partial\xi/\partial x = 0$, which is equivalent to the vanishing of the excess pressure. The use of a probe microphone confirms this approximately by direct experimentation. It yields, as stated, the normal modes given by equation (67) and these are in approximate agreement with experiment.

Exact agreement is not obtained since the air at the end of the tube has inertia and must be disturbed by the wave traveling along the tube. Moreover, the disturbance at the end of the tube acts effectively as an acoustic source radiating into the open air, leading to loss of energy. Empirically, this latter phenomenon has only a small effect on the characteristic frequencies of the tube, but the former can be quite noticeable. Consider a tube closed at one end and open at the other. Application of the ideal boundary conditions just mentioned then leads to the set of characteristic frequencies

$$\nu_n = (n + \tfrac{1}{2})\, c/2l \tag{69}$$

but because of the open-end effect these are modified to

$$\nu_n' = (n + \tfrac{1}{2})\, c/2(l + S/C) \tag{70}$$

where S is the area of cross section of the tube and C (with dimensions of length) is known as the acoustic conductivity of the opening. It is difficult to compute C theoretically but for a circular opening it is of the order of magnitude of the diameter. Hence the term S/C in this case is approximately $\pi a/2$, where a is the radius of the circular tube. The characteristic frequencies are thus those of a tube of equivalent length $l + \pi a/2$, which for a short wide tube can be rather different from l. In general the quantity S/C is known as the end correction. It can be evaluated by direct measurement of the normal modes and is a useful method of obtaining C.

In the actual wave disturbance corresponding to a normal mode in a tube open at both ends, there are positions in the tube, specifically for

$$\cos n\pi x/l = 0 \tag{71}$$

at which the displacement is zero at all times. This cannot take place in a progressive wave; thus the wave disturbance corresponding to a normal mode is known as a standing wave. The positions of continuous null displacement are known as nodes, while the positions for which $\cos n\pi x/l = 1$ are called antinodes or loops, corresponding to maximum displacement. The distance between successive nodes is equal to a half wavelength of the particular mode. From the relation between displacement and excess pressure a displacement node is an excess pressure antinode and

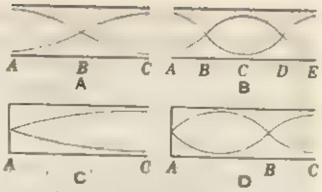

FIG. 12.—STANDING WAVES

(A) Fundamental or first harmonic and (B) second harmonic in tube open at both ends; (C) first harmonic and (D) second harmonic in tube open only at one end

vice versa. The tube is shown open at both ends in fig. 12 (A) and (B). Here in (A) A and C are antinodes and B (at centre) is a node. In (B) A, C, and E are antinodes and B and D ($\frac{1}{4}$ and $\frac{3}{4}$ of the distance along the tube) are nodes. The tube open at one end and closed at the other is exemplified in fig. 12 (C) and (D). In (C) A is a node and C an antinode. (All this refers to the phenomena of displacement.)

The resultant particle displacement in the standing wave produced by arbitrary initial conditions in a tube of length l open at both ends is taken to be the sum over all the normal modes; *i.e.*,

$$\xi = \sum_{n=0}^{\infty}(A_n \cos n\pi c/l \cdot t + B_n \sin n\pi c/l \cdot t) \cos n\pi x/l \qquad (72)$$

The assumption is known as the principle of superposition and was enunciated by D. Bernoulli in 1755. It is the basis for the Fourier analysis of an arbitrary disturbance in a finite medium into harmonic modes (*see* FOURIER SERIES).

From equation (72) the initial displacement at any point x in the tube is

$$\xi_0(x) = \sum A_n \cos n\pi x/l \qquad (73)$$

while the initial velocity is

$$\dot{\xi}_0(x) = \sum n\pi c/l \cdot B_n \cos n\pi x/l \qquad (74)$$

The dot in $\dot{\xi}_0(x)$ denotes partial differentiation with respect to time. Note that $\xi_0(x)$ and $\dot{\xi}_0(x)$, though presumably arbitrary, are here represented as sums of harmonic components in x. The evaluation of the coefficients A_n and B_n proceeds according to the Fourier rule and it is found that

$$A_n = 2/l \cdot \int_0^l \xi_0(x) \cos n\pi x/l \cdot dx \qquad (75)$$

$$B_n = 2/n\pi c \cdot \int_0^l \dot{\xi}_0(x) \cos n\pi x/l \cdot dx \qquad (76)$$

This assumes the mathematical validity of the expansion. Physically possible forms for $\xi_0(x)$ and $\dot{\xi}_0(x)$ in general satisfy the mathematical conditions.

In addition to sound disturbances propagated in a cylindrical tube, the same type of analysis can be applied to any confined space; *e.g.*, a room with or without open windows. The reflection of the disturbance from the boundaries of the room produces a three-dimensional standing wave pattern that can be analyzed into a set of normal modes or characteristic frequencies depending on the shape and dimensions of the room. Some of these modes may be much more prominent than others and have a good deal to do with the acoustics in the room; absorption at the walls and in the air itself plays an important role.

16. Wave Pulses; Group Velocity.—Thus far attention has been restricted to the propagation of continuous progressive waves like

$$\xi = A \cos(\omega t - kx) \qquad (77)$$

in which for given x there are nonvanishing displacements no matter what t is, and vice versa, or standing waves like

$$\xi = A \sin \omega t \cdot \sin kx \qquad (78)$$

where again the displacement occurs for all x and all t. These are ideal situations. Instead of finding the wave of equation (77), in practice, waves are encountered in which the disturbance at any instant is localized in a bounded region of space as in fig. 13, which pictures the disturbance at the instant t as a function of x.

FIG. 13

From infinity on the left up to A, the value of ξ is zero; from A to B, the value of ξ is given by equation (77), and from B to infinity on the right ξ is again zero. This is known as a finite wave train or wave pulse. As time passes, the train moves from left to right carrying the disturbance with it. In empirically producible wave disturbances this is what is found.

A wave pulse may be represented by a superposition of continuous and infinite harmonic wave trains, like equation (77), if the frequencies do not form a discrete set like the normal modes in a tube; the method requires infinitely many continuously distributed frequencies. The amplitude of each harmonic component depends on its frequency or wavelength and may become negligibly small for sufficiently great and small frequencies; thus the band of frequencies necessary for the harmonic decomposition of the pulse effectively will be finite if the pulse is finite in length. For example, consider the pulse

$$\begin{aligned} \xi(x - ct) &= \cos k_0(x - ct), & |x - ct| &< L/2 \\ \xi(x - ct) &= 0, & |x - ct| &> L/2 \end{aligned} \qquad (79)$$

which is the situation pictured in fig. 13. The amplitude $A(k)$ of the harmonic component corresponding to wave parameter k then is

$$A(k) \doteq \frac{\sin(k_0 - k)L/2}{\pi(k_0 - k)} \qquad (80)$$

By plotting $A(k)$ as a function of $(k_0 - k)$ it is found that the range of wave parameter k necessary to represent the traveling pulse adequately is inversely proportional to L, the length of the pulse. A very long wave train therefore needs only a very small range of parameter to represent it and in the limit of $L \rightarrow \infty$, the train becomes $\cos k_0(x - ct)$ precisely. If the pulse is very short $k_0 - k$ becomes correspondingly large.

These considerations apply only if the wave velocity c is independent of the frequency or wave parameter. If there is dispersion the situation is more complicated. On the assumption that only a finite range Δk of wave parameter about a mean parameter k_0 is adequate for the representation of the pulse, the wave train can be expressed approximately as a single sinusoidal wave of angular frequency ω_0 with an amplitude that is a function of time and space through the quantity

$$x - (d\omega/dk)_0 t \qquad (81)$$

The meaning of $(d\omega/dk)_0$ is that the dispersion of the medium is expressed by writing ω as a function of k:

$$\omega = \omega(k) \qquad (82)$$

Then differentiate ω with respect to k and take the value of the derivative corresponding to $k = k_0$. A point proceeding in the x direction with velocity

$$U = (d\omega/dk)_0 \qquad (83)$$

will always be at same amplitude. If it travels at this velocity with the maximum amplitude it will be a point where the individual harmonic components in the original wave train heap up, so to speak, to form what may be called a wave group. The velocity of progress of the group is called the group velocity and is given by equation (83).

The group velocity also can be conveniently expressed as

$$U = \frac{c_0}{1 - (\nu/c_0)(dc/d\nu)_0} \qquad (84)$$

where the phase velocity c is expressed as a function of the frequency ν, and c_0 is the mean phase velocity in the group. If $c = c_0$, a constant $U = c_0$ independent of frequency and of the group velocity coincides with the constant phase velocity. Since acoustic dispersion in fluids is generally very small over obtainable frequency ranges (save for hydrogen), the group velocity will not in general differ much from the phase velocity. At any rate in the use of short-pulse techniques for measuring acoustic velocity in fluids it is the group velocity that is measured. In dispersion associated with fluid viscosity, heat conduction, and relaxational effects, the velocity in general increases with the frequency. Hence $dc/d\nu > 0$ and $U > c_0$: the group velocity is greater than the

average phase velocity; this is opposite to the case of normal dispersion of light.

The advantage of short-wave pulses in measuring acoustic properties is that undesirable reflections can be separated from the main beam. The echo method of acoustic depth recording as well as gun ranging and the detection of submerged objects in water (sonar) depend on the use of pulse techniques.

From its definition, it may be assumed that the group velocity is that with which the energy in the wave train is transmitted. This holds approximately, but requires more consideration than will be given here.

It is often desirable to amplify an acoustic pulse by transforming it into an electrical pulse in an oscillating circuit and then feeding it into an amplifier. If the original shape of the pulse is to survive amplification undistorted the uniform frequency response of the amplifier must cover a sufficiently large band of frequencies. Thus, for the pulse considered in the example above, the frequency band must correspond to a wave-parameter band satisfying the approximate condition

$$(k_0 - k)\ L/2 \doteq \pi \tag{85}$$

17. Radiation Pressure.—Thus far when the pressure associated with an acoustic wave has been mentioned, it referred to the excess pressure produced by the disturbance and propagated through the medium. For a plane harmonic progressive wave the excess pressure is a sinusoidally varying function of time and space and hence vanishes if averaged over the time at any particular place. It does of course have a nonvanishing mean square value. However, associated with a progressive acoustic wave in any physically realizable medium there is also a pressure that does not vanish on the average, thus making a net addition to the static pressure prevailing in the medium. This is known as the radiation pressure. It is a so-called second-order quantity because it is much smaller than the root-mean-square (square root of the average of the square) acoustic excess pressure. In the ordinary acoustic equations as developed here it is therefore usually neglected. However, it is always present because of the essential nonlinearity of the acoustical equations if higher-order terms are included. This means that if the particle displacement in an acoustic wave has the form of equation (3), the corresponding acoustic excess pressure will be made up not merely of a corresponding linear term proportional to sin $(\omega t - kx)$ but also a term proportional to $\sin^2 (\omega t - kx)$, with a much smaller coefficient of proportionality. This latter term, when averaged over time, gives rise to the steady radiation pressure.

The simplest expression for the radiation pressure is

$$p_r = \frac{p_e \partial\xi/\partial t}{c} \tag{86}$$

where p_e is the root-mean-square excess acoustic pressure and $\partial\xi/\partial t$ is the root-mean-square particle velocity. Since the latter is always smaller than the wave velocity c, it follows that $p_r << p_e$. In spite of its small value relative to p_e, the radiation pressure p_r produces some important consequences. Its existence implies that any solid object in the path of an acoustic beam will undergo a steady pressure.

This may be used to estimate the acoustic intensity, since p_r is directly proportional to the intensity (*see* section V.1 below). Moreover, under some conditions p_r is associated with the production of steady streaming of the fluid medium through which the sound wave is passing. This streaming may produce interesting physical effects (section V.6 below).

18. Shock Waves.—In a macrosonic or high-intensity sound wave, a disturbance that starts out with a symmetrical profile (fig. 2) will very soon develop a steepening of the wave front. This process is opposed in fluids like air or water by the attenuation mechanisms mentioned in section II.13.

The result can be a saw-toothed curve (fig. 14) in which at points *A, B, C,* and so on, there are considerable changes in pressure over a very small space. Ideally there is a genuine discontinuity in pressure, density, and flow velocity at these points. Empirically there is no discontinuity, but the drop in pressure or density occurs over an interval order of 10^{-4} cm. in a gas under standard conditions; *i.e.*, about 10 mean free paths of the fluid. This transition state moves through the medium faster than the normal acoustic velocity. Called a shock wave it can result from an explosion or from a solid object (*e.g.*, a missile or airplane) moving through a fluid faster than acoustic velocity. Shock waves can be observed in a tube through the sudden rupture of a membrane separating a region of high pressure from one of low pressure. The thickness of a shock front, as it is called, can be estimated from its optical reflectivity (associated with the change in the index of refraction) or by the change in temperature through it. Shock fronts can be studied with an optical interferometer; the rapid change in density across the front produces a shift in the interference fringes. The strength of a shock is defined as the ratio of the pressure just ahead of the front to that just behind it.

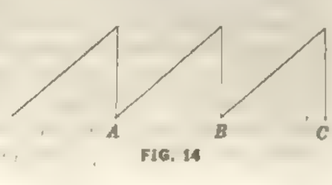

FIG. 14

A shock wave is reflected by an obstacle, but the law of reflection for ordinary low-amplitude waves is followed only for angles less than about 40° for strong shocks. For larger angles the reflection is complicated. Similar considerations apply to refraction and diffraction. By the 1960s there was an extensive literature on shock waves and their significance in physics and chemistry (*e.g.*, *see* AERODYNAMICS: *Supersonic Aerodynamics;* AERONAUTICS. *Airfoils: Shock-Wave Phenomena;* EXPLOSIVES: *Deflagration and Detonation*).

III. ACOUSTIC SOURCES

1. Introduction.—Sound-wave disturbances must be produced before they can be propagated. An appropriate change in the density at a point in an elastic medium may be said to be a source of sound. This accounts for the great variety of sound sources, since density change may be produced in many ways, including mechanical, thermal, electrical, magnetic, and chemical actions. The most common sound waves are periodic or considered as compounded of periodic (harmonic) components. The simplest and most important sources are vibrating portions of solids, liquids, and gases.

2. Damped and Forced Vibrations.—In a mechanical vibrator any portion of the system that is displaced from equilibrium tends to return to its undisplaced condition. Such a vibrator is characterized by a mass or inertia factor m; a stiffness factor f representing the elastic tendency to return to the equilibrium state, and a damping factor R, representing the tendency for the motion resulting from the original disturbance to decay instead of continuing forever. Consider a weight suspended from an ideally weightless spring fastened to a rigid ceiling. When the weight is displaced from rest position and let go, it tends to move to the original position. The inertia factor here is the mass of the weight, the stiffness factor is the applied force per unit stretch of the spring, and the damping factor is provided by the internal friction of the spring, by the viscosity of the surrounding medium (*i.e.*, the air), and by the loss of energy to the medium as sound radiation. This is not generally an efficient sound source. A membrane that presents a larger vibrating and radiating area to the medium is more practical, although assignment of the three vibrational factors is more difficult. For example, though the equivalent mass of the vibrator is proportional to the mass of the membrane it is not equal to it (*see* section III.5 below). However, there is great analytical advantage in treating any vibrator in terms of these factors.

The equation of motion of a vibrator with a displacement from equilibrium denoted ξ is

$$m\ddot{\xi} + R\dot{\xi} + f\xi = 0 \tag{87}$$

where again the dot denotes time differentiation; *i.e.*, $\ddot{\xi} = \dfrac{d^2\xi}{dt^2}$. The form of the solution depends on the interrelation of m, R, and F. If

$$f > R^2/4m \tag{88}$$

vibrations result and the solution is

$$\xi = Ae^{-Rt/2m}\cdot\cos(\omega t+\alpha) \tag{89}$$

where e is the base for natural logarithms,

$$\omega = \sqrt{f/m - R^2/4m^2} = 2\pi\nu \tag{90}$$

and ν is the frequency of the vibrations. A is called the initial amplitude and α is the initial phase angle or epoch of the motion. Because of the term $e^{-Rt/2m}$ the amplitude of the oscillations steadily diminishes with time and ξ plotted as a function of t appears as in fig. 15. This is called a damped oscillation; equation (89) describes its so-called free vibration; *i.e.,* uninfluenced by any outside force. The extent of the damping is described by $2m/R$, called the decay modulus. Alternatively, the logarithmic decrement δ is used; it is the natural logarithm of the ratio of two successive maxima of the ξ, t curve, and is given by

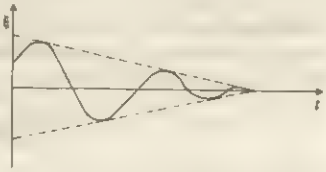

FIG. 15

$$\delta = RP/2m \tag{91}$$

where P $(= 1/\nu)$ is the period of the vibrations (*i.e.,* the time for one complete to-and-fro motion of the vibrating mass, or the time from one maximum of the curve in fig. 15 to the next. The larger R is for given P, the larger is δ and the more rapid is the decay.

For acoustic applications in which electric circuits are the source of mechanical oscillations, the so-called quality factor Q is used to describe the damping. In terms of the logarithmic decrement this takes the form

$$Q = \pi/\delta \tag{92}$$

Thus a highly damped oscillator is said to have a low Q and vice versa.

The quantities A and α depend on the initial conditions of the motion. If the value of ξ at $t = 0$ is ξ_0 and that of the displacement velocity $\dot{\xi}$ is $\dot{\xi}_0$ then

$$A = \sqrt{\xi_0^2 + (\dot{\xi}_0 + R\xi_0/2m)^2/\omega^2} \tag{93}$$

$$\alpha = \arctan\left(-\frac{\dot{\xi}_0 + R\xi_0/2m}{\omega\xi_0}\right) \tag{94}$$

If $f < R^2/4m$ (*i.e.,* if there is relatively large damping) there are no vibrations and ξ makes a single swing and decays to zero. Such overdamped systems are not considered in steady state acoustics, though they can serve as sources of sound pulses.

The average rate of dissipation of energy of the vibrating system due to the damping force is

$$\overline{\dot{E}} = -\overline{R\dot{\xi}^2} \tag{95}$$

where the bar indicates the average taken over an arbitrary time interval. If $\overline{\xi^2{}_{\max}}$ denotes the mean-square amplitude over the time interval

$$\overline{\dot{E}} \doteq -R\omega^2\overline{\xi^2_{\max}}/2 \tag{96}$$

If the damping arose entirely from radiation of acoustical energy into the surrounding medium, equation (96) would give the acoustically radiated power output. This is never the case, however; in general the power output is some proper fraction of $\dot{\mathrm{E}}$, measuring thereby the acoustical efficiency of the source.

Damped vibrations provide only a transient sound source. To maintain steady oscillations an external force must be applied. If the force varies harmonically with angular frequency ω_0 and amplitude F_0 the system will reach a steady state of vibration with the same angular frequency, which in general will differ from the free vibration frequency of equation (90). The steady state displacement has the form

$$\xi = \frac{F_0\cos(\omega_0 t - \beta)}{\sqrt{\omega_0^2R^2 + (f - m\omega_0^2)^2}} \tag{97}$$

where

$$\beta = \arctan(\omega_0R/[f - m\omega_0^2]) \tag{98}$$

is the phase angle between the force and the displacement. Other things being equal, the smaller the damping factor R, the more nearly ξ is in phase with the force or 180° out of phase with it.

In some ways the velocity is more significant. Here

$$\dot{\xi} = \frac{F_0\cos(\omega_0 t - \gamma)}{\sqrt{R^2 + (m\omega_0 - f/\omega_0)^2}} \tag{99}$$

where

$$\gamma = \arctan\left(\frac{m\omega_0 - f/\omega_0}{R}\right) \tag{100}$$

is the phase angle between force and velocity; clearly $\beta = \pi/2 - \gamma$. Both ξ and $\dot{\xi}$ are harmonic in time with frequency $\nu_0 = \omega_0/2\pi$. The amplitude of $\dot{\xi}$ is a maximum for

$$\omega_0 = \sqrt{f/m} \tag{101}$$

and this is called the resonance (angular) frequency ω_{res} of the system. In words, when the frequency of the force is adjusted to $1/2\pi\cdot\sqrt{f/m}$, the system is said to resonate with the force and maximum steady state velocity oscillations ensue. The displacement does not attain maximum steady state amplitude at resonance but at the frequency

$$\nu_1 = \tfrac{1}{2\pi}\cdot\sqrt{f/m - R^2/2m^2} \tag{102}$$

If $R^2/2m^2 << f/m$, this is close to the resonance frequency and to the free oscillation frequency of equation (90).

The analogy with electrical oscillations of an L, R, C circuit is striking. The denominator in the right-hand side of equation (99) is called the mechanical impedance of the vibrator. Thus

$$Z = \sqrt{R^2 + (m\omega_0 - f/\omega_0)^2} \tag{103}$$

is a minimum for resonance and equal to the damping factor R.

Since the harmonic force maintains the system in a steady state of vibration, the average rate of energy flow from the source of the force to the system just equals the average rate of dissipation of energy through the damping as indicated in equation (95). This average flow of energy is a maximum at resonance.

If the amplitude of $\dot{\xi}$ is plotted as a function of $\omega_0 - \omega_{\text{res}}$, a so-called resonance curve results. The maximum $\dot{\xi}$ occurs at $\omega_0 - \omega_{\text{res}} = 0$ and decreases on either side of the origin. The nature of the resonance peak is controlled by the damping factor R. If R is small the peak is high and sharp; if R is large the peak is low and broad. In the first case the response of the system to the force is more selective with respect to frequency than in the second.

3. Coupled Systems.—As has been emphasized, the vibrations of a single mass particle are only an idealized representation of sound-source motions. Actual sound sources are extended bodies or collections of particles, like strings, membranes, rods, and plates. Such sources may be thought of as collections of vibrating particles coupled together. A simple illustration is provided by two mass particles attached to a weightless, stretched, flexible, horizontal string of finite length. If the particles move in a vertical plane only, the motion of each is affected by that of the other through the tension of the string joining them. The vibrations of such a system correspond to the superposition of component vibrations of two different frequencies, even if the masses are the same and the attachment to the string is perfectly symmetrical. The generalization of this situation is that of n particles attached at regular intervals to the stretched string (the so-called loaded string). There are now n characteristic frequencies and the motion of each particle is a superposition of n harmonic components with these n different frequencies. Finally, as n increases indefinitely the system should act more and more like a continuous string. Mathematically the string is treated not as a collection of discrete particles but as a continuous medium (albeit linear) somewhat like a one-dimensional continuous elastic fluid that exhibits wave motion when disturbed from equilibrium.

4. Strings; the Helmholtz Resonator.—If an indefinitely long horizontal flexible string of mass ρ_l per unit length is stretched

with tension T along the x axis any disturbance represented by a transverse displacement ξ from the equilibrium (rest) position is propagated in accordance with the wave equation (R. B. Lindsay)

$$\frac{\partial^2 \xi}{\partial t^2} = T/\rho_l \cdot \frac{\partial^2 \xi}{\partial x^2} \quad (104)$$

the solution of which corresponds to transverse waves propagated along the string with velocity

$$c = \sqrt{T/\rho_l} \quad (105)$$

If the string is of finite length l, and fastened at both ends, the solution of equation (104) that satisfies the boundary conditions $\xi = 0$ at $x = 0$ and $x = l$ is of the same form as that discussed in section II.15 above. Thus the motion of the string is compounded of a series of harmonic standing waves or normal modes of vibration with frequencies given by

$$\nu_n = nc/2l \quad (106)$$

where n is integral. The relative importance of the various modes in any given motion of the string depends on the initial conditions; *i.e.*, the methods used to excite the string into vibration. Commonly these are plucking (harp, mandolin), striking (piano), and bowing (violin). Each of these methods in turn permits considerable variation in the nature of the acoustic output depending on where the initial disturbance is produced. When a string is plucked at the centre, for example, all the even harmonics are absent, seriously affecting the musical quality of the emitted waves. Plucking near one end restores all the harmonics and improves the quality. The nature of the plucking instrument also is of importance. The struck string involves more elaborate considerations, since the impact of the hammer is a complicated function of the time. All harmonics having a node at the point where the string is struck will have zero amplitude. Bowing is the most complicated way of exciting a string, since the communication of energy to the string is more or less continuous. The oscillation is a special kind of forced vibration that may be properly called self-maintained.

The transmission of energy to a string by bowing is not precisely like the forced vibrations considered earlier since the force in this case is not harmonic. The string receives energy from the bowing, but the frequency of vibration is conditioned by the string itself, its mounting, and the position of the bow. The resulting oscillations are often termed auto-oscillations or self-maintained oscillations. Their mathematical study can be facilitated by treating the force as a kind of negative damping. Another acoustic illustration is provided by the blown organ pipe (jet-edge tones). The electrical oscillations produced by an ordinary simple vacuum tube circuit are also of this character.

The output of sound energy from a vibrating string depends on its surroundings; *i.e.*, the presence of other resonating systems such as air cavities and solid baffles (*see* STRINGED INSTRUMENTS).
